

his limbs tremble, his mouth is dry, he feels he will fall or collapse or die ; he turns pale, his pulse-rate changes, usually becoming more rapid, his blood-pressure rises, he may want to open his bowels or pass his urine. When anxiety is long-standing and severe, such attacks are rare. It is possible for parts of this general affective disturbance to be isolated, and to occur with little conscious anxiety, as in muco-membranous colitis, effort-syndrome, aerophagy, neurotic indigestion, enuresis, impotence, ejaculatio præcox, psychogenic asthma, hyperidrosis. The factors determining such special emphasis on one or other system are partly physical (some organic defect or innate functional anomaly) and partly psychological. In anxiety thyroid enlargement can occur ; weight falls off ; menstruation is irregular or ceases ; the deep reflexes are very active.

Diagnosis.—Typical cases are easy to recognise. The common errors of diagnosis lie in : (1) Missing organic disease (*e.g.* general paralysis, cerebral arterio-sclerosis) ; or the converse (*e.g.* mistaking the more expansive manic patient for a general paralytic). (2) Forgetting how mixed the symptoms of mania, melancholia, and anxiety may be, so giving rise to atypical pictures that may be mistaken for schizophrenia, if too superficial an examination or too static and rigid a diagnostic criterion be used. (3) Forgetting the influences of age, general personality, and milieu on the content of a patient's mind, *e.g.* his having lived among spiritualists may lead to deceptively fantastic statements. (4) Expecting to be able to diagnose solely on presenting symptoms, without regard to previous history and constitution ; the reverse is also to be avoided. (5) Expecting diagnosis always to lie between distinct entities which could not possibly be mixed together in the same person, as though hysteria were incompatible with affective psychosis, or both of these with schizophrenia ; in fact, they often are mingled. This is not to make light of diagnosis, which gives the psychiatrist much knowledge that he cannot gain from study of the individual case before him.

Nothing in the mental state of a patient with affective disorder may enable one to exclude an organic basis such as general paralysis or cerebral arterio-sclerosis. This decision must turn on the physical findings. The problem becomes simpler when signs of dementia supervene. (See p. 1857.)

From schizophrenia, diagnosis depends on a picture of the whole illness, on the presence of characteristic thought-disorder, incongruity of affect and bizarreness of behaviour, as well as on the previous personality and constitution, rather than on any positive features of affective psychosis ; the remoteness and unconvincing manner of the schizophrenic, so hard to describe but almost conclusive when recognised, may help. Later, when complaints have become empty and repetitive to the point of stereotypy, and catatonic symptoms mix with the anxiety, diagnosis is easier. As between schizophrenic and manic excitement, the setting in which the excitement occurs is almost more important than the *prima facie* symptoms. In young people schizophrenic features may often be found without their being of much significance ; in the elderly what seem to be catatonic features may rest on an organic cerebral basis. The more easily one can get in touch with the patient, enter into his mood and understand what he says and does, the more is it an affective, not a schizophrenic disorder. The range of benign affective phenomena is wider than a textbook description can convey.

TEXTBOOK OF THE PRACTICE OF MEDICINE

BY VARIOUS AUTHORS

EDITED BY

FREDERICK W. PRICE

M.D., C.M., F.R.C.P., F.R.S.ED.

CONSULTING PHYSICIAN TO THE ROYAL NORTHERN HOSPITAL AND TO
THE NATIONAL HOSPITAL FOR DISEASES OF THE HEART, LONDON

reliability, they cannot be translated into the language and recommendations of practical life unless the interpreter has a clear knowledge of the theoretical and technical limitations implicit in their method. To take a "self-administering" test or a group test of intelligence and to draw merely from the score obtained on it by a child or adult the conclusion that he is mentally defective, would be as inept and gross an error as to diagnose active syphilis merely because an unknown laboratory on one occasion reported a positive Wasserman reaction in the patient's blood.

There are general observations about mental tests which it is particularly necessary for occasional or inexperienced testers to bear in mind. The scores must be accurately and as far as possible objectively arrived at; therefore the personal opinion of the tester should not enter into them, though his skill in administration may have influenced the result. Any test which has not been standardised on an appropriate population cannot be safely employed, since test scores have no absolute significance; they must always be compared with "norms," and it is imperative that these norms shall have been collected on a suitable group since it would be misleading, for example, to judge an English child to be less intelligent than an American one because he could not do a test requiring familiarity with American habits and ideas. A test, to be satisfactory, must be both reliable (measuring the subject's ability accurately and consistently) and valid (correlating effectively with other measures of the ability that is being tested). The validation of intelligence tests is a difficult matter: sometimes it is carried out by comparing test-scores with ratings of intelligence by teachers and other judges or with subsequent educational achievement, and sometimes by the statistical procedure of factorial analysis in which all the items in the test are compared with each other to see whether there is internal consistency.

Intelligence tests are different from educational tests. They are intended to measure native ability, not acquired experience. It is true that educational attainment depends largely on innate qualities, but the more an intelligence test relies on tasks which demand some acquirement not equally available to all those tested, the more misleading may be its results. The application of this to verbal tests is obvious; a subject who has poor command of English or who has aphasia cannot do himself justice on a test that is satisfactory for the bulk of literate people. Performance tests, which do not use words, are not entirely free from similar defects, and in spite of certain merits (greater attractiveness for children, tendency to evoke informative temperamental reactions) have conspicuous disadvantages; they are seldom cheap or handy, are often inconsistent and unreliable, and have poor validity; on some of them the subject's performance is much influenced by any emotional or neurotic disturbance he may have. Consequently, whereas a single predominantly verbal test like the Binet may suffice to indicate the child's or adult's intelligence (provided there is no special verbal difficulty), it would be unsafe to rely on one, or even two or three, performance tests; a median or average score based on half a dozen performance tests is preferable.

Group tests have become increasingly popular because they save so much time. They are not suitable for testing young children (under the age of 7 or 8); are not so objective and standardised in application as they seem, are by no means foolproof, depending as they do to some degree on the subject's attitude and situation at the time, about which the group-tester will know little or

There are two new illustrations (Figs. 2 and 5). Fig. 91 has b Apart from the original validity of conception, I attribut this textbook to the high abilities and devoted efforts of my contributors, with whom, from the beginning, my relationship ha most intimate and happy character. Only those with experie understand the self-sacrifice which they have exhibited. No can adequately express my admiration and gratitude for their can do is to tender them my most cordial thanks. It is also a ve duty to express my warm appreciation to the publishers and th Editor, Mr. G. T. Hollis, for their co-operation.

As the progenitor and editor of the first seven editions of t may not be inappropriate if, on this occasion, I made the following remarks. Its sale abroad almost equals that in the United Kingdo in my view, is evidence of the international prestige of British In the nature of things, all the contributors were. hospitals. From the inco thirty-nine contributors w me, only one inquired whc would labours. This, in my opinion, is indicative of medical profession in this country.

It is my earnest hope that this new editio than it forerunners, of service alike to Tes Physicians, General Practitioners, and Senic continue to be regarded as worthy of British I

PREFACE TO FIRST EDITION

Molluscum... generally recognised that within recent years there has been a great
 The following knowledge throughout the domain of Medicine. As an example
 Septicæmia, might be cited the branch of cardiology. As the result of, the intro-
 Paratyphoid, the clinical polygraph and of the electro-cardiograph we are now
 Typhoid Fever, to analyse the cardiac action in a manner which was never possible
 Lead Poisoning, and many of the problems in the study of diseases of the heart which
 Scurvy, and Acromegaly, baffled clinicians for generations have been practically solved, while
 of Hypoparathyroidism are in process of solution. In the department of neurology the
 of Oral Surgery made has been scarcely less notable. It seemed to me, therefore,
 the Parotid Gland, now, more than ever, it has to be acknowledged that it is beyond the
 Acute Tonsillitis, any authority, however varied his range of knowledge, to do full
 spasm), Neurology, to the ever-widening field of Medicine, and that a useful purpose
 treatment, might be served by the publication of a work of moderate compass and
 in Children, a volume, in which the different branches of Medicine were dealt with
 acute Appendicitis, by workers who have made a special study of them. It has also been thought
 Subacute, to include sections on Diseases of the Skin and Psychological
 Blood Grafting, Tropical Diseases are also included.
 Asthma, Rheumatism, Tropical Diseases are also included.

A TEXTBOOK OF THE PRACTICE OF MEDICINE

SECTION I

INFECTION

EFFECTS OF BACTERIAL ACTIVITY

WHEN a bacterial invasion of the body tissues occurs the result is disease ; the process is spoken of as an infection, and the bacterium is said to be pathogenic. The terms "pathogenic" and "non-pathogenic" are by no means rigid. No organism is pathogenic to all animals, and even organisms generally pathogenic to a given species may be introduced into an individual of that species, even in considerable quantity, without producing disease. On the other hand, organisms usually saprophytic, when introduced in sufficient quantity into an animal of a species usually immune, may cause disease.

Organisms pathogenic for one species of animal are frequently non-pathogenic for other species, and not a few organisms are pathogenic for man alone, except under certain exceptional experimental conditions.

Certain organisms which habitually exist under normal conditions as saprophytes in one part of an animal's body, may at the same time be the cause of an active infection in another part. For example, a member of the coliform group of intestinal bacilli, usually a harmless saprophyte in the intestine, may be simultaneously the cause of an active infection in the bladder. Bacteria which usually function as harmless saprophytes, but under certain conditions become pathogenic, are termed "commensals." Again, micro-organisms that are potentially infective may and do exist under saprophytic conditions ; that is to say, apart from the animal body, and under different conditions as regards temperature, etc. Saprophytic bacteria that are incapable of invading living animal tissues may yet invade the animal body when any part thereof is so injured as to be dead, or is in process of dying. Certain varieties of bacteria, usually infective, may become saprophytic. The hosts are then termed "carriers." The best known examples thereof are the typhoid bacillus, the diphtheria bacillus and the meningococcus. The two former examples generally, if not always, occur after an infection, whereas the meningococcus is more often found existing in a saprophytic than in a pathogenic state. In these cases the bacteria do not exert any apparent harmful effect, but they are, of course, of great potential danger to the surrounding community.

A similar condition exists in connection with the paratyphoid bacilli and those of the food-poisoning group generally. This condition differs to some slight extent from that of the carriers noted above, in that there is some evidence, continuous or recurrent, of constitutional disturbance, though

in the periods between recurrence, which may be prolonged, the condition closely resembles that of a carrier.

Infective bacteria are generally aerobic, or facultatively aerobic. True anaerobes have very little power of spreading through uninjured animal tissues unless they are accompanied by aerobes, though they may cause localised infections in tissues in which the oxygen supply is limited. Hence the bacteria usually associated with infections are aerobic organisms that flourish at body temperature.

A microbe may belong to a highly infective variety and yet its infectivity vary greatly. This property is known as *virulence*, and depends on various factors.

The *path of infection* also has a determining influence. Thus, staphylococci injected subcutaneously in a rabbit produce a local abscess, while if the injection be intravenous, pyæmic abscesses may lead to death. Typhoid bacilli must be swallowed to be infective, while it has been demonstrated that plague may be caused by rubbing *B. pestis* into the skin.

Subject of infection.—Healthy individuals differ greatly in their reaction to infective microbes, because of individual, racial or environmental characteristics, or because of age.

A *local susceptibility* may be brought about by trauma or interference with the circulation, conditions which may permit even anaerobic organisms to flourish.

An existing disease may modify the reaction of the host to an infection. Thus the subjects of diabetes are prone to staphylococcal and tuberculous infections.

Bacteria that are capable of spreading in the tissues usually have the power of causing *septicæmia*, that is, of flourishing in the blood stream, and, as a sequel, of producing *pyæmic* processes. Other bacteria causing acute infections appear in the blood stream during the earlier stages of the infection, but in the later stages tend to disappear therefrom, the *bacteriæmia* being incidental to, but not coextensive with, the infection. Streptococci and staphylococci are common examples of the former process, and the typhoid bacillus of the latter.

RESULTS OF BACTERIAL INFECTION

If the individual be in a healthy state, even a large quantity of virulent micro-organisms can gain admission to the body, and, owing to the local defences, may be destroyed before damage occurs; such a repelled invasion may cause no symptoms. When the local defences prove inadequate to ensure the complete destruction of the invading bacteria, the result is a local, or general, infection, or both.

A local infection may result in cellulitis or abscess formation, associated with more or less absorption of poisonous products; such a local infection may become generalised, leading to septicæmia or pyæmia. But whether the infection be local or general, or both, a greater or less degree of general poisoning may occur, by reason of soluble poisons elaborated by the bacteria. These poisons are termed "*toxins*." *Toxins* are of two varieties—*exotoxins* and *endotoxins*.

Exotoxins are soluble poisons elaborated by certain classes of bacteria—

notably diphtheria and tetanus. These exotoxins are destroyed by comparatively low temperatures; for instance, diphtheria toxin is destroyed by a temperature of 65° C. When an exotoxin is introduced into an animal's body, the specific effects thereof appear after an incubation period. *Endotoxins* can only be recovered by autolysis or trituration of the micro-organisms which produce them. This means that those bacteria which only elaborate endotoxins can only poison an animal by proliferating within the tissues of that animal, while the poisoning produced by exotoxin may occur without invasion of the body by the organism concerned. Endotoxins will withstand a temperature of 100° C.

The difference between exotoxin and endotoxin is a fundamental one in specific therapy, as in a toxæmia from exotoxin a suitable antitoxin in appropriate amount constitutes an adequate defence, while in the case of toxæmia from an endotoxin the bacterium itself has to be proceeded against. The mode of action of toxins is very variable and depends upon the variety of bacterium. The toxins of diphtheria and tetanus tend to produce profound poisoning effects on the nerve tissues. Those consequent upon other infections produce other effects, prominently fever and degenerative changes in the tissues.

IMMUNITY

Definition.—Immunity is that function of the animal organism by virtue of which the effects of bacterial activity are resisted. Immunity is either natural or acquired.

NATURAL IMMUNITY

Factors determining immunity are not well understood; but environment, habits, age and race partly account for them. The natives of countries where certain diseases are endemic may be far more resistant to those diseases than inhabitants of countries where the diseases are not endemic, as shown by the resistance of the negro to yellow fever. Conversely, diseases that have existed in mild forms for years endemically among one race may cause a veritable plague when introduced to a fresh race. Thus tuberculosis ravaged the North American Indians, and syphilis when introduced to Europe from America, where it was probably endemic, followed the course of an epidemic of a highly contagious disease.

There is also individual immunity, as shown by the fact that in any epidemic some individuals entirely escape infection, while in those infected all degrees of resistance are noted. In contradistinction to individual natural immunity, which condition does not lend itself to analysis, there is the condition of individual susceptibility—a condition to which considerable study has been devoted, chiefly in the direction of non-bacterial toxæmias, such as hay fever and the various toxic idiopathies.

ACQUIRED IMMUNITY

(i) *As the result of recovery from infection*

When an individual has recovered from certain infections such as typhoid fever, scarlet fever, measles and the other exanthemata, he commonly experiences immunity from those diseases in future. The duration of this

form of acquired immunity varies greatly with different infections: that following influenza and pneumonia may be quite short. This acquired immunity was recognised centuries ago, and history shows that attempts at protection were made by inoculating infective material; it was on account of this knowledge that Pasteur began the study of protective inoculation which forms the basis of our knowledge of immunity.

(ii) *Artificial Immunity; Active and Passive*

Pasteur, in 1880, showed that injections of attenuated cultures of the organism of chicken cholera would protect the inoculated fowl against lethal doses of the virulent bacilli. From this observation resulted artificial immunity, and because the protection is elaborated solely by the action of the tissues of the infected animal, the term Active Immunisation was introduced by Ehrlich.

Von Behring, in 1890, discovered that the serum of actively immunised animals when transferred to other animals conferred immunity on the latter, and this process is termed Passive Immunity. It differs broadly from active immunity in that the protection afforded is comparatively transient, depending as it does on the actual amount of immune substance introduced.

ANTITOXINS

As already stated, toxins are of two kinds—exotoxins and endotoxins. The former exert their effects independently of the bacteria that produce them, while the latter only become effective when their parent microbes become dissolved. The injection of suitable doses of exotoxin calls forth the response of antitoxin; whereas the injection of suitable doses of endotoxin, *i.e.* vaccine, calls forth the response of bacterial antibodies. It is now known that other bacteria than those of diphtheria, tetanus and Shiga's dysentery produce appreciable quantities of antitoxin, namely *Streptococcus scarlatinae*, *B. botulinus* and *Staphylococcus pyogenes*.

Since von Behring and Kitasato demonstrated the antitoxic properties of the blood of animals immunised against diphtheria toxin in 1890, an immense amount of work has been published, and improvements in the preparation of antitoxin have constantly accrued.

A unit of toxin is that quantity sufficient to kill a 250 g. guinea-pig in 4 days. The original Ehrlich unit of antitoxin was that amount that would save the life of a 250 g. guinea-pig injected with 100 units of toxin, but owing to variations in the strength and keeping qualities of different batches of toxin, the present unit of antitoxin is the amount of antitoxin in a known weight of dried antitoxic serum preserved in England, the United States of America and Germany.

The preparation of diphtheria and tetanus antitoxins is comparatively simple, as is also the preparation of scarlatina antitoxin, but the preparation of powerful staphylococcal antitoxin is proving difficult.

Other anti-sera of therapeutic value are those prepared against infection by meningococcus, pneumococcus, streptococcus, anthrax, clostridium welchii, *B. dysenteriae* and leptospira icterohæmorrhagiae. The use of several of these sera has been considerably restricted since the recent expansion of chemotherapy.

THE PROPERTIES OF IMMUNE SERA

Von Behring's discovery that the sera of immune animals could passively confer immunity shows that such immune sera contain substances either different from those, or in excess of those, present in normal sera; and, in 1894, Pfeiffer showed that if cholera spirilla were injected into the peritoneal cavity of a highly immunised guinea-pig, the bacilli lost motility, became granular and swollen, and finally disappeared. This phenomenon became known as Pfeiffer's phenomenon, or Bacteriolysis. It was then shown by Metchnikoff and Bordet that a similar result occurred *in vitro* in a mixture of heated immune serum and cholera vibrios if, and only if, normal serum be added. As a result of these and subsequent researches it was recognised that two substances are present in immune sera, one of which is peculiar to immune and the other common to immune and normal sera. The former, originally called "substance sensibilisatrice" (Bordet), is now generally known as *amboceptor* (Ehrlich); while the latter, formerly called alexin by French writers, is now usually known as *complement* (Ehrlich).

It will also be recognised that the specific change that has occurred in an immune serum is the presence of amboceptor, which can only act in the presence of complement. Amboceptor is specific in that it only acts in connection with the bacterium or inoculating substance which calls it forth (antigen), while complement acts independently and in connection with amboceptor of any kind.

Bacteriolysis also occurs in connection with typhoid immune sera, but many other varieties of bacteria are not subject to it; it can, however, be demonstrated that those organisms, immunity against which is unaccompanied by bacteriolysis, are susceptible to other properties of immune sera. In connection, however, with bacteriolysis must be mentioned hæmolysis. Bordet, in 1898, showed that if an animal be immunised with the corpuscles of another species the serum of the immune animal acquires the property of destroying the red corpuscles of that species. This phenomenon of hæmolysis has become of great importance, as it forms the indicating phenomenon in the complement deviation test of Bordet and Gengou, and of its modification the Wassermann reaction. Similarly many other cytotoxic sera can be elaborated by injecting emulsions of appropriate cells.

Agglutinins.—The agglutination of bacteria in the presence of the serum of an immune animal was first observed by Charrin and Roger in 1889, and as a specific reaction was described by Gruber and Durham in 1896, when Grünbaum and Widal simultaneously recognised the great importance of this reaction from a diagnostic point of view in the case of typhoid fever.

If bacterial substance be introduced into the tissues of an animal, either by infection or injection, agglutinin is formed, and will cause agglutination of the agglutinable substance in an emulsion of the homologous bacteria. The bacterial substance is an antigen, and inasmuch as it appears to be identical with the agglutinable substance, the latter is also frequently alluded to as antigen.

Agglutination occurs in two stages. In the first, sensitisation of the bacteria by a specific substance in the immune serum, agglutinin, occurs: and in the second, the bacteria adhere together, in clumps, and gradually settle

by gravity. Such clumping only occurs in the presence of low dilutions of salts, acting as electrolytes.

Agglutination does not affect the vitality of bacteria, and it occurs with living or dead bacteria. Agglutinins are relatively thermostable, though an agglutinating serum which has been heated to between 62° to 70° C., or which has been kept for a long time, may show "zones" of agglutination, i.e. that with low and high dilutions of serum agglutination occurs, but with intermediate dilutions there may be no agglutination.

Among motile bacteria two types of antigen occur, the flagellar termed H, and the somatic termed O, and the agglutinins resulting from each have different characteristics. H agglutination results in large loose flakes, and H antigen is usually labile at temperatures of from 80° to 100° C., while the O agglutination results in small compact flakes, and the antigen resists a temperature of 100°. The H agglutinins tend to persist in an animal serum for a long time, and also tend to reappear in a patient's blood during a non-specific fever, so care must be exercised in reading a moderately high agglutination as diagnostic of the existence of infections of the enterica group. These considerations do not hold in connection with diseases such as undulant fever, or dysentery, as the O agglutinins do not tend to persist, or to be regenerated by non-specific fevers. In general, H agglutinations are rapid and may be read after 2 hours. O agglutinations are less rapid, and are seen at their best after 12 hours. The H antigens are generally more specific than the O antigens. For example, the O antigens of *B. typhosus* and *enteritidis* are very similar, if not identical, but their H antigens are quite specific. In the case of the *Proteus* group, however, the O antigens are far more specific than the H antigens within the limits of the group.

Felix and Pitt have shown that in the case of the typhoid bacillus, and possibly also in *Salmonella* infections, there is a marked difference in smooth strains, in that some are far more virulent than others. They have shown that strains recently isolated tend to be virulent because they possess a "Vi" antigen in addition to the H and O antigens of the smooth type of typhoid bacillus. The virulence of any smooth type being examined is tested by the intraperitoneal injection of mice, the test dose being 100×10^6 bacilli.

Vi antigen is heat labile, and agglutinative tests to demonstrate its presence must be carefully carried out with living suspensions at body temperature.

In practice the patient's serum, in a series of graded dilutions, is mixed with suspensions of fresh or preserved bacteria, and the mixtures incubated at 55° C. The highest dilution of serum containing specific agglutinins varies within wide limits according to the nature and state of the infection.

With regard to the enterica group, the following are usually considered as diagnostic :

<i>B. typhosus</i>	.	.	.	1 in 64 or higher.
<i>B. paratyphosus</i> A	.	.	.	1 in 32 or higher.
<i>B. paratyphosus</i> B	.	.	.	1 in 128 or higher.

For classifying bacteria recovered from patients, specific immune sera are employed, the titre of which will be known, and the limits of agglutination denoting pathogenicity indicated.

Precipitins.—To a filtrate of cholera vibrios Kraus added anti-cholera serum, and incubated the mixture at 37°. After some time flocculi appeared. The

same phenomenon occurred with typhoid filtrates and anti-typhoid serum, and in the course of time precipitating sera were prepared against a great variety of antigens, animal, bacterial and vegetable. It was found by Danyasz, subsequently elaborated by Dean, that optimal proportions of antibody and antigen played an important part in the successful performance of the test, and it appears that a relative excess of either hinders the reaction. The strength of sodium chloride solution used has some effect also on the reaction, and Dean has shown that 0.2 per cent. is the most favourable. Originally it was thought that precipitin so acted on antigen—precipitinogen—as to precipitate the protein thereof, but it has been shown by many workers that the bulk of the precipitate is derived from the proteins of the antiserum. This is in obvious contrast to the agglutination reaction, in which the agglutinated bacteria are clearly derived from the agglutinin.

The reaction is turned to account in Forensic Medicine, in the recognition of human blood in blood stains, in the recognition of the meat of different species of animals, and even in the detection of cereal adulterants. Methods of estimation of the strengths of toxins and antitoxins are also based on the precipitin reaction.

Anaphylaxis.—When a foreign protein is introduced into an animal, hyper-susceptibility may be produced, which hyper-susceptibility can be demonstrated by injecting after the lapse of ten days a further—in itself non-lethal—dose of the protein, when there occurs a condition varying from slight signs of illness ranging through various stages of respiratory distress up to sudden death. A second injection of antitoxin after a sufficient interval may produce anaphylaxis. In consequence of this the question of desensitisation becomes of great importance. If at some period more than 10 days after an injection of antitoxin it is desired to give a further dose the presence of the anaphylactic state should be negatived. This is done by a skin reaction. A small quantity, say 0.05 c.c., of normal horse serum (or antitoxin) is injected intradermally, or rubbed into a scarified surface. There occurs, if anaphylaxis—or a toxic idiosyncrasy to horse substance—exists, an urticarial patch sometimes progressing to a vesicular eruption with a surrounding area of erythema. This usually occurs within half an hour, but is occasionally delayed. If anaphylaxis be demonstrated, the patient should be desensitised. If time be not of paramount importance, 0.025 c.c. of antitoxin is administered subcutaneously, and the amount is doubled every half hour. After 1 c.c. has been given, subsequent doses are given intravenously until 25 c.c. in all have been administered. If any reaction follows a dose, that same dose is repeated in half an hour. When serum is being given to a patient whose idiosyncrasy is unknown, 1 c.c. of 1 in 1000 adrenaline in a syringe should be at hand lest symptoms of anaphylaxis should appear. A similar method of desensitisation may be carried out for patients allergic to liver extract, etc.

Serum sickness.—The use of horse serum, whether normal or immunised, and especially when given by the subcutaneous route, often leads to certain symptoms of a non-specific character on or about the eighth day after the first dose has been administered. These symptoms consist of an urticarial rash, with pruritus which may be very troublesome, mild pyrexia, pain in and swelling of the joints and some malaise. The urticaria may be concentrated about the site of injection of the serum, or it may be generalised.

There may be local or general œdema, but the latter is uncommon ; so, too, are albuminuria and swelling of the lymph glands. In some cases the local urticaria appears much earlier than the eighth day ; it may appear within a few hours of the initial puncture, the more general symptoms showing themselves towards the end of the week. "Serum sickness" is rarely serious. Treatment is by anti-pruritic lotions, such as saturated bicarbonate of soda solution, or dilute carbolic acid (1 : 100) or lotio calaminæ co, and by aspirin internally. It may be added that if the joint symptoms precede the rash—a rare event—some difficulty may arise in diagnosis.

THE FILTRABLE VIRUSES

A number of human diseases, examples of which are small-pox, rabies, yellow fever, chicken-pox, measles and epidemic poliomyelitis, are now known to be caused by ultra-microscopic viruses, and, arguing from analogy, encephalitis lethargica is thought to belong to the group, though proof is still lacking.

As a rule, these viruses measure less than $250\ \mu\mu$, and some of them measure much less. Particles less than $250\ \mu\mu$ cannot be resolved by ordinary microscopes, though Barnard, by the use of a short-wave ultra-violet light and lens systems of quartz has resolved objects as minute as $75\ \mu\mu$. Great diversity of size occurs amongst the viruses. For instance, that of foot-and-mouth disease of cattle measures about $12\ \mu\mu$, while that of pleuro-pneumonia of cattle, which occurs in two forms, measures from $150\ \mu\mu$ to $250\ \mu\mu$. With few exceptions, however, the viruses are ultra-microscopic, and will pass through filters that fail to pass the ordinary bacteria. The properties of the porcelain filters used vary considerably, and other factors besides the actual diameter of the pores have to be taken into account. Thus, the substance of the filter may adsorb the virus, even though the pores of the filter may be sufficiently large for its passage. The flexibility of the virus, and the pressure of filtration may also introduce variable factors. It follows, therefore, that the failure of a virus to pass through a filter does not necessarily mean that its particles are too large.

Though differing much in size and effects, most of the viruses have characteristics in common. Many of the diseases caused by filtrable viruses in man and animals are highly infectious, very minute doses of virus causing infection—an infection that spreads with great rapidity. Many of the virus diseases produce special intracellular bodies, termed inclusion bodies. These may be restricted to one particular tissue, or may be found in various tissues. They may occur in the cytoplasm or nuclei of cells, or in both, and vary greatly in size. In some diseases the diagnosis can be made histologically by the recognition of these bodies, e.g. the Negri bodies in rabies. The fact that the inclusion bodies have been seen to develop *in vitro* in tissue-cultures suggests that the filtrable viruses are intracellular parasites, in which respect they differ from the majority of bacteria.

Some of the virus diseases, such as yellow fever, dengue and papataci fever, are insect-borne.

With the exception of pleuro-pneumonia of cattle, no virus has been cultivated *in vitro* in the absence of growing cells, though many can be

propagated in tissue cultures, and on account of this exception, many, if not the majority of workers, hold the opinion that pleuro-pneumonia is not a virus disease. Generally speaking, therefore, viruses can only be propagated by animal passage.

Most of the viruses produce an active immunity which is very lasting, and in some of the diseases immune serum confers passive immunity. In measles the injection of immune serum will produce such a degree of passive immunity as to prevent an attack of measles in a contact, but such immunity is not lasting. If given about 6 days after contact, a modified attack of measles of very attenuated type will occur, subsequent to which permanent immunity ensues. Valuable clinical results have been claimed by many workers from the use of immune serum in the pre-paralytic stage of poliomyelitis, but the exact value of the method is difficult to assess. With few exceptions all agree that immune serum has no effect when once paralysis has supervened. Recent work published by the Rockefeller Institute shows that fully inactivated yellow fever virus will not confer immunity. Inactivated distemper virus will, however, immunise, and is indeed used as a preliminary measure in the prophylaxis of distemper, and inactivated virus also confers immunity in cattle plague, fowl plague, rabies, influenza (in mice), herpes and some other animal diseases.

Most of the filtrable viruses are resistant to glycerine, especially at low temperature, and remain unaltered for long periods in 50 per cent. thereof at 4° C., whereas the lethal effect of glycerine on bacteria generally is well known.

Complement fixation reactions between virus and antibody have been shown in many virus infections, and flocculation has been shown in the case of variola virus. Ledingham has shown that homogeneous suspensions of the elementary corpuscles from vaccinia and fowl-pox are agglutinated by the sera of convalescent animals, while normal serum has not this effect.

The following list comprises some of the human virus diseases under three headings :

1. *Certain*

Small-pox.	Herpes Febrilis.
Chicken-pox.	Herpes Zoster.
Mumps.	Infectious Warts.
Yellow Fever.	Acute Anterior Poliomyelitis.
Dengue Fever.	Psittacosis.
Phlebotomus Fever.	Rabies.
Rift Valley Fever.	Encephalitis (St. Louis Type)
Lymphogranuloma Inguinale	Influenza.

2. *Almost Certain*

Measles.	Molluscum Contagiosum.
Encephalitis Lethargica.	Rubella.

3. *Possible*

Common Cold.

BACTERIOPHAGE

In cultures of bacteria certain areas of transparency, increasing at the expense of the growth, have been recognised for years by bacteriologists, but had not attracted much attention, being dismissed as due to autolysis, until, in 1915, Twort found that the process could be transferred to fresh cultures indefinitely. He also showed that the lytic principle could be transferred in filtrates free of bacteria. He discussed the possibility of an ultra-microscopic virus being responsible.

D'Herelle, in 1917, carried out an important research on the phenomenon, and maintained that the lysis was due to an ultra-microscopic virus, to which he gave the name "Bacteriophage."

Much controversy has arisen as to the true nature of bacteriophage, two main opinions emerging—(1) that it is a living ultra-microscopic virus, and (2) that it is a ferment supplied by the bacteria themselves. All authorities appear to agree that the actual lytic agent is an enzyme, but disagree as to the origin of the enzyme.

Bacteriophage is very resistant to many influences deleterious to bacteria. Many specimens require 75° C. for half an hour to ensure destruction. Freezes sealed up in tubes for more than a year may still show bacteriophage. D'Herelle found it withstood 1 in 200 perchloride of mercury and 1 in 100 carbolic for 3 days.

Usually a bacteriophage to one organism has no effect upon a different variety, though a certain amount of overlapping with allied strains occurs.

Bacteriophage can act as an antigen, and when injected into an animal produces an antiserum which inhibits the lytic action.

A. E. GOW.

PENICILLIN

Penicillin is the name given by Fleming in 1929 to an antibacterial substance produced by a species of mould (*Penicillium Notatum*), which in 1929 contaminated a culture plate which had been planted with staphylococci. Fleming noticed that around the mould colony the staphylococcal colonies were undergoing lysis, and so he grew the mould in pure culture and studied the properties of the antibacterial substance—penicillin. Since that time penicillin has been used in the laboratory for differential culture, but early attempts to extract the active principle failed, and it was not till 1939 that Chain, Florey and their co-workers, at Oxford, succeeded in concentrating the penicillin sufficiently to reveal its remarkable chemotherapeutic properties.

Many other moulds have been tested, and besides *P. notatum* other members of the *Chrysogenum* group have been shown to produce penicillin but not so satisfactorily as *P. notatum*, and it is from this that all penicillin is manufactured.

The penicillin issued for treatment is a yellow powder, consisting of 30 to 50 per cent. of the sodium or calcium salt. It is very soluble in water, but the solutions are unstable and must be preserved in the refrigerator

The strength of the penicillin and its dosage is calculated in terms of the Oxford Unit, a standard assessed by comparison with a standard product.

Penicillin exerts the most extraordinary antiseptic powers against the gram-positive species of bacteria, notably the pneumococci, the streptococci, and the staphylococci, and in regard to the last organism its powers are much greater than those of the sulphonamides—indeed, pure penicillin can inhibit the growth of staphylococci even when its concentration is as little as 1 in 50,000,000. This antibacterial substance has also proved highly successful with the gram-negative organisms gonococci and meningococci.

A list of susceptible and insusceptible organisms is as follows :

<i>Susceptible</i>	<i>Insusceptible</i>
Pneumococci.	Gram-negative organisms, in general.
Streptococci.	B. typhosus and the salmonella group.
Staphylococci.	The viruses in general and Influenza.
The gas-gangrene group of organisms.	B. Pertussis.
B. anthracis.	The brucellæ.
C. Diphtheria.	B. pestis.
Actinomyces.	V. Cholera.
Spirochæta Pallida	B. dysenteriæ.
Spirillæ generally.	B. pyocyaneus and proteus.
Gonococci.	M. tuberculosis.
Meningococci.	Enterococci.

For penicillin to act, it is necessary to get it in contact with the infective bacteria. This can be done by injecting it intravenously, intramuscularly, or subcutaneously. It then gets into the blood and reaches the infected area, but it is rapidly excreted by the kidney so that injections have to be repeated frequently. After intramuscular injection penicillin is at its maximum concentration in the blood in 10 or 15 minutes, and therefore little is gained by intravenous injections. Probably the most convenient method in general is by intramuscular drip.

The dose is from 60,000 to 120,000 units in 24 hours, administered by continuous drip, or three-hourly injections of 15,000 units.

In addition to its extraordinary antiseptic power, penicillin has two other attributes of outstanding value. It is almost non-toxic to the body as a whole, the leucocytes and cells of which are in no way affected deleteriously by any reasonable concentration of the drug. Moreover, penicillin is almost completely indifferent to the medium in which it acts, whatever be the protein content thereof, acting as well in serum, blood and even in pus, as in broth.

JOHN MATTHEWS.

SECTION II

GENERAL INFECTIOUS DISEASES

A. BACTERIAL DISEASES

THE main results of the invasion and infection of the body by micro-organisms are discussed in the section upon infection and immunity. It is important to distinguish clearly between "invasion," "infection" and "intoxication," and the reader is referred to the section mentioned for the consideration of these several processes.

TOXÆMIA

This term is applied to the condition of a patient who is absorbing into the tissues and circulation toxins elaborated at some local site of microbic infection. The diseases caused by the specific microbes of diphtheria and tetanus are examples of toxæmia, the sites of infection being in the former disease the fauces or larynx, and in the latter disease the damaged tissue about a wound or abrasion. The symptoms of toxæmia are variable, and depend upon the special affinity that the toxins concerned have for certain tissues or organs. There are, therefore, general symptoms common to many microbic infections: fever, rigors, malaise, vomiting, pains in the back and limbs, headache, sweating, etc.; and special symptoms, such as are manifested by an affinity of the toxin for nerve structures (paralyses, spasms, delirium, etc.), or for the heart (arrythmia, tachycardia, cardiac asthenia, etc.), and others.

One form of toxæmia of great importance is that known as *Focal Sepsis*. In this condition there may be few or no symptoms referable to the primary local site of infection, yet the resulting toxæmia may manifest itself as fibrositis, arthritis, anæmia, rarefaction of bone, loss of weight, pyrexia, or a combination of these. In focal sepsis, pyrexia is not a marked feature except in some cases of coliform infection of the urinary tract and in a minority of dental apical infections. The likely sites for focal sepsis are the nasal sinuses, the teeth, the tonsils, the bronchi, the gall-bladder, the appendix, the intestinal tract and the genito-urinary tract in both sexes. Chronic infection may lurk in certain of these situations even in the absence of gross macroscopic lesions. The tonsils, for example, though not enlarged, may contain pus or inspissated secretion in their crypts: a scarred and ragged tonsil, or one which has venules on its surface is always suspect, especially when the lymph node behind the angle of the jaw is palpable. The search for focal sepsis must be thorough and systematic, and may necessitate certain instrumental investigations, e.g. X-ray examination of the cranial sinuses, of the apices of the teeth and the periodontal membranes; a cholecystogram; a catheter for a specimen of urine; a speculum for a view of the cervix uteri.

Bacteriological examination of a post-nasal swab, or of the apex of a tooth at the time of extraction, or of a catheter specimen of urine, of any uterine discharge, of material obtained after prostatic massage, or of the stools, etc., may be required. The correct interpretation of the findings from such investigations is often difficult.

SEPTICÆMIA

Septicæmia is a condition in which the infecting microbe transgresses the tissue barrier at the site of local infection and invades the blood stream, multiplying therein, and thus continuing the infection in a general manner. The mere existence of the microbe in the blood stream is not to be considered as necessarily constituting a true septicæmia. Thus we know that during the first few days of an attack of typhoid fever, of pneumonia, and of certain other diseases, the specific microbe can very often be isolated from the circulation by blood culture. The more thoroughly the investigation of microbic infections by blood culture is undertaken, the more patent it becomes that at some stage or other the infecting organism exists in the circulation. *Bacteriæmia* is a convenient term by which to express the (temporary) existence of micro-organisms in the blood stream in other states than true septicæmia.

There are two main conditions of septicæmia in so far as this is related to the local infection. (1) The local infection may be obvious, the septicæmia clearly resulting from this; or (2) no local infection may be discoverable, or the local infection may be, at best, merely surmised. Even at a careful post-mortem examination the source of local infection may not be manifest in some of the cases illustrating this type of septicæmia.

The microbes chiefly concerned in septicæmia are *Staphylococcus aureus*, *Streptococcus pyogenes* (vel *hæmolyticus*) and the pneumococcus. Much less commonly the gonococcus, Pfeiffer's bacillus, the meningococcus, and *B. pyocyaneus* perform this rôle.

The local infections tending to lead to septicæmia are chiefly concerned with the throat (streptococcus), the uterus ("puerperal fevers"), the subcutaneous tissues of the hand and foot (infections during operations and post-mortem examinations, septic wounds, etc.), and the site of surgical operations (post-operative septicæmia).

Symptoms.—The symptoms in septicæmia vary much; there is also great variation in the intensity and course of the disease. Some of the worst cases from the point of view of prognosis are those in which physical signs are conspicuous by their absence, whether as regards the site of the local infection or as regards the development of secondary lesions (thromboses, visceral inflammations, etc.). Thus, in a case of puerperal septicæmia, if a careful examination of the pelvic organs reveals no defect in the uterus or its adnexa, and if no signs of local concentration of the infecting agent be found elsewhere, the case is likely to be one of great anxiety.

The symptoms include pyrexia, usually considerable in degree, and most often intermittent in character. Rigors are not uncommon, though by no means constant. The patient is generally free from pain and local discomforts, but feels exhausted and very ill. The mental state is usually normal; in some cases the outlook is disproportionately optimistic. Sweats

are common, especially if the pyrexia is markedly intermittent. Diarrhoea may occur. Some degree of general abdominal distension is common. The spleen may be palpable. The pulse is quickened, the pulse tension lowered, and there may be subjective cardiac disturbances related to the toxic myocarditis which is an invariable result of the main pathological process. A progressive hæmolytic anæmia is one of the most striking features in most septicæmias, both clinically and upon examination of the blood. The leucocytes vary a good deal, and their number constitutes a helpful point in prognosis: the smaller the count the worse the outlook. Loss of weight is not a noticeable symptom, except in cases which become "chronic," nor must the absence of this feature lead, of itself, to a favourable view as to the outlook. Erythemata are often seen, both diffuse and discrete, especially in cases due to streptococcus infection; they are prone to be evanescent. Purpura is not uncommon. Joint pains and swellings are also common, and these not seldom disappear without any metastatic abscess formation. Pleurisy and pericarditis are not infrequent in staphylococcus infection.

Prognosis.—The prognosis is serious in all cases of septicæmia, though less so now than formerly. This is partly because, as the result of the earlier and more extensive use of blood cultures, more cases are recognised, and partly because the exploitation of chemotherapy has added useful treatment in many instances of the disease. Of serious import are the following: rigors, the absence of signs of the local infection, the absence of a leucocytosis, rapid progression in the associated anæmia, early dilatation of the heart, vomiting, pleurisy, insomnia, and delirium or stupor.

Treatment (see pp. 17–20).

PYÆMIA

When septicæmia is complicated by the formation of multiple abscesses, or of multiple foci of tissue necrosis, the clinical condition is conveniently spoken of as pyæmia.

All pyæmic patients are septicæmic, but not all septicæmic patients are pyæmic. Some septicæmias tend to be pyæmias from the first, in other cases there is a late development of the pyæmia after a period of simple septicæmia lasting for days or, it may be, weeks. In the great majority of cases of pyæmia the primary infection is obvious.

There are three types of pyæmia according to the anatomical distribution of the primary infection in relation to the circulation.

1. *Systemic venous pyæmia*.—This is the form which is seen in osteomyelitis due to *Staphylococcus aureus*, in suppurating wounds (staphylococcus, streptococcus, *B. coli*, etc.), in suppurations of the urinary and bronchial tracts and in suppurating dermatitis and cellulitis. The metastatic abscesses form in the lungs, kidneys, perirenal tissues, joints, bones, and, less often, in the heart wall and in the brain. The symptoms are those of a severe septicæmia together with those of the disease-processes set up by the focal events just referred to. Some of the cases are of long duration, and when this is so the patient is apt to become very emaciated.

2. *Portal pyæmia* (suppurating pylephlebitis).—This is the form of pyæmia resulting from certain pyogenic infections in the alimentary tract—rectum, colon, appendix, gall-bladder and elsewhere. The infection follows in ascend-

ing fashion the radicles of the portal vein, setting up a septic thrombosis and ultimately causing multiple abscesses in the liver. The symptoms are those of a severe febrile illness with acute or subacute abdominal signs, moderate jaundice, and an enlarging liver. The diagnosis is sometimes difficult, but when indubitable the prognosis is extremely grave. The micro-organisms concerned are generally of the coliform group, or streptococcus; mixed infection is not uncommon.

3. *Arterial pyæmia*.—This form of pyæmia is seen in septic endocarditis, with which disease it is, for the most part, identical. The focus of primary infection, so far as the pyæmic process is concerned, is the endocardium, and especially of the valves, where colonisation of microbes takes place, and whence innumerable septic emboli proceed into the arterial system. Seeing that in the great majority of the cases this focus occurs on the left side of the heart the emboli, if they set up metastatic areas of infection, do so in organs and tissues supplied by the systemic vessels: spleen, brain, kidneys, limbs, etc. In the less common instances, where the endocarditic focus is on the right side of the heart, the infection being grafted upon a congenital lesion, the emboli lodge in the pulmonary vessels, producing multiple infarcts in the lung, usually with associated pleurisy.

The microbes most often causing septic endocarditis are organisms of feeble virulence (streptococci of the salivary and fæcal groups, or *H. influenza*); this fact accounts for the infrequency of suppuration in the infarcted areas occurring in this disease. When, however, the endocarditis is due to such virulent microbes as *Staphylococcus aureus* and *Streptococcus pyogenes*, abscess formation does occur in the infarcts.

Treatment (see pp. 17-20).

TERMINAL INFECTION

Micro-organisms which are found in the tissues in the course of a post-mortem examination are related to them in four different ways: (i) They may be the primary infection leading to the disease-process which causes death. (ii) They may be present as secondary infection, in association with the primary infection, and they may or may not be largely responsible for the death of the patient. (iii) They may be present as a "terminal infection," the disease-process from which the patient suffered being not itself manifestly of microbic origin, but one tending to lower the tissue resistance to infection. The terminal infection in these cases generally, as the name implies, precipitates the lethal event, or actually causes it. (iv) They may be present merely as an agonal or sub-mortem invasion, or even as a post-mortem invasion. It is necessary carefully to distinguish between the last two of these relations. The mere isolation of organisms from certain tissues (*e.g.* the mucoid material of the middle ear) in the post-mortem room does not prove that they were present in these situations during life, still less that they were operative by way of actual infection. It is even doubtful if the cultivation of organisms from the blood of the heart, or from the cerebro-spinal fluid, after death, give evidence of infection during life, though some authorities consider that it does. Much depends, of course, upon the conditions at the time of the investigation.

Terminal infection does certainly occur, however, in well-recognised form

and quite distinct from sub-mortem invasion. The organisms most often responsible for the condition are the less virulent strains of streptococci (*S. salivarius* and *S. faecalis*), the coliform group, staphylococci and the tubercle bacillus. *B. proteus* and *B. aerogenes capsulatus* are also found to operate in this manner at times.

The disease-processes in which terminal infection frequently occurs are cirrhosis of the liver, granular kidney, diabetes, leukaemia and morbus cordis. There is a latent form of septic endocarditis (most often streptococcal in origin) which is also of the nature of a terminal infection. Serous membrane tuberculosis, and especially peritonitis, is quite common in cirrhosis of the liver. Many of the patients in whom this terminal infection occurs are so ill at the time the event arrives that it frequently goes undiscovered, partly because their responses to infection are feeble and partly because clinical examination is difficult.

STREPTOCOCCUS INFECTION

The streptococci form a group of micro-organisms in which the different members vary greatly in virulence. They also vary in their morphological and cultural features and in their biochemical reactions. There is, therefore, no little difficulty experienced in any effort at successful classification. Broadly speaking, there are two main groups of the microbe. (1) There is the highly virulent group called *Streptococcus pyogenes* to which the alternative name *Streptococcus haemolyticus* is applied, on account of its property of haemolysing when cultivated on blood-agar. (2) And there is the more feebly virulent group *S. viridans* including the variants *S. salivarius* and *S. faecalis* of some authorities. The first type is usually seen in long and curling chains when recently isolated, and the second is usually seen in short chains of two, four, or some number of relatively few members.

S. pyogenes (vel *S. erysipelatosus*; *S. haemolyticus*) is the causative microbe in erysipelas, in acute abscess formation, in acute cellulitis and lymphangitis, in severe operation and post-mortem infections when these are of streptococcus origin, and in the more virulent streptococcus infections complicating the puerperium, influenza, scarlet fever, and some other specific fevers.

S. viridans (*S. salivarius* and *S. faecalis*) is found in association with pyorrhoea alveolaris, with secondary streptococcus infection in rheumatic fever, with arthritis occurring in connection with focal infections, and with most chronic and subchronic infections of streptococcal origin. The streptococci found in the heart valves, and in the blood stream in cases of subacute septic endocarditis, are for the most part of this nature.

The clinical results of streptococcus infection vary according as the infection is by the first or by the second of these types of the microbe. In infection by *S. haemolyticus* the disease-process is usually acute and often fulminant. Septicaemia results not infrequently, and pyaemia is not uncommon. If endocarditis results from the infection and embolism occurs, the infarcts suppurate. In infection by *S. viridans* the disease-process is prone to be chronic, or at most subacute. Septicaemia is uncommon, except in association

with endocarditis, in which condition embolic infarcts proceed to coagulative necrosis, but not to abscess formation.

Treatment (see below).

TREATMENT OF THE FOREGOING INFECTIVE PROCESSES

A. GENERAL MEASURES.—These include rest, ample nutritious diet, abundant fresh air, the control of fever by hydrotherapeutic means, and the maintenance of a cheerful outlook in the patient and in his medical attendant. The nursing of these "septic" patients is of great importance, and experience of similar cases is a great asset.

B. DRUGS.—Formerly very intractable, many of these diseases have recently come largely under control by the use of the sulphonamide group of bacteriostatic drugs. Sulphanilamide; sulfanilamide, U.S.P.; (colsulanyde; prontosil album; streptocide; sulphonamide P.) is the more efficient drug in combating infection due to streptococcus hæmolyticus. Sulphapyridine (Degenan; M. & B. 693) is especially useful against the pneumococcus and the gonococcus. Meningococcus and coliform infections, other than the typhoid group, respond well to either. Infections due to staphylococcus aureus are frequently controlled by sulphathiazole; streptococcus viridans has so far resisted this group of drugs. Whatever preparation is chosen it should be given intensively and the oral route is to be preferred whenever possible. In most cases the following scheme applies for an adult: grm. 2 of the drug are given as an initial dose, followed by grm. 1·5 every 4 hours for 2 to 3 days, then grm. 1 four-hourly for 2 days, and finally grm. 1 six-hourly for 2 days. Children in proportion to their weight have a higher tolerance than adults; up to the age of 3 years each dose may be grm. 0·5, at the age of 12, grm. 1 may be given.

The administration of a sulphonamide should not be prolonged beyond the seventh day, or 2 to 3 days after the fever has subsided. Sulphadimethylpyrimidine ("sulphamezathine") is more rapidly absorbed and less rapidly excreted, and so the requisite blood concentration may be maintained by less frequent doses. The initial dose of grm. 4 is succeeded by grm. 2 every six hours. In fulminating cases the intravenous route is chosen, at any rate for the initial dose; sodium sulphonamide must not be injected into the theca.

Cyanosis consequent on the administration of sulphanilamide may be due either to methæmoglobinæmia or to sulphæmoglobinæmia, the latter being more frequent; when following sulphapyridine (Dagenan; M. and B. 693) it is usually the result of methæmoglobinæmia (Campbell and Morgan). Methylene blue, 0·5 grm. in cachet twice daily by mouth, will diminish cyanosis due to methæmoglobin but is without effect on sulphæmoglobin, which may persist for several weeks after the drug has been discontinued. Phenacetin, and other similar drugs, which may produce methæmoglobin should not be prescribed at the same time as a member of this group; aspirin may be employed to relieve pain. Vomiting is often troublesome; it may be relieved by draughts of sodium bicarbonate solution. Occasionally it is so severe that administration of the drug by mouth must be (temporarily) abandoned in favour of the intravenous injection of the soluble sodium salt in 10 per cent.

solution. Urticaria and morbilliform eruptions may occur. Tachypnoea and hæmaturia are seldom serious complications, but the development of acute hæmolytic anæmia or of agranulocytosis calls for immediate suspension of the drug. It has been noted that pyrexia may persist after an acute febrile illness has seemingly responded successfully to this form of chemotherapy, or follow a brief apyrexial period—a "sulphonamide fever" which settles when the drug is stopped. Should it be necessary to suspend sulphonamide therapy on account of any untoward reaction to the drug, fluids must be pushed by mouth to aid excretion, and sufficient alkali given to maintain the urine alkaline in reaction.

A recent addition to the chemotherapy of coecal infections is penicillin. Its range of effective action is wide, but not all strains of these organisms are sensitive to it. With this qualification, penicillin is indicated in any case which proves to be resistant to sulphonamide. It must be administered by intramuscular or intravenous injection, as it is inactivated by the acid of the gastric juice and by enzymes from coliform bacilli in the rectum.

To control the progressive anæmia, over and above the general measures, arsenic is perhaps the most useful remedy; it may be given conveniently as sodium cacodylate, gr. 1, once or twice daily, in the form of intramuscular injection. The writers often combine it with nucleic acid, a useful stimulant to leucocytosis, in the following formula:

R. Sod. cacodylatis, gr. 1.
Ac. nucleici (sat.) ad min. 15.

In agranulocytosis the intramuscular injection of 10 c.c. of pentnucleotide is indicated; the injection must be made very slowly and may be given twice in the 24 hours.

C. SURGERY.—All abscesses developing in the course of a pyæmia must be drained forthwith, either by aspiration or by free incision, the former for preference and, if practicable, especially in patients who are very ill. When dental extractions are indicated in the treatment of focal sepsis, not more than two or three teeth should be extracted at one sitting; a local anæsthetic should not be employed save when regional injection (nerve block) is possible. In such a case the site of injection must be at some distance from the site of sepsis, as there is grave danger of spreading sepsis by injecting into a septic tissue. Experience proves it to be most unwise to remove teeth at the same time that the patient is undergoing any other surgical operation.

D. TRANSFUSION OF BLOOD.—This measure is often most helpful, especially to combat severe anæmia, or so to improve the patient's general condition that he may be in a better state to derive benefit from other remedies.

E. SPECIFIC THERAPY.—Measures which may be used to combat the infection by way of immune therapy are, it goes without saying, of much greater theoretical importance than those which act non-specifically. Unfortunately our knowledge of efficient specific remedies grows very slowly, and there are many gaps and guesses in it. All the same, careful consideration should be given in every case to the nature of the infection, and to the question if some form of specific treatment, whether by immune serum or by vaccine, or by both, may not be of service.

1. *Streptococcus Infection.*

(a) *Hæmolytic streptococcus infections.*—These include acute septicæmia, puerperal fever, certain complications of scarlet fever, erysipelas and acute cellulitis, in which "scarlet fever" antitoxin serum and sensitised *Streptococcus pyogenes* vaccine are the agents now chiefly used in immuno-therapy. Scarlet fever antitoxin has largely replaced the original *Streptococcus pyogenes* antiserum, but if no benefit is observed after the use of the former remedy recourse should be had to the latter. Concentrated serum should be given as early as possible: 10 or 20 c.c. intramuscularly, repeating 10 c.c. eight hourly as need be. Sensitised vaccine is made from strains of *S. pyogenes* recently isolated from several sources, and may be given in doses of 100, 250 and 500 millions subcutaneously on three successive days.

(b) *Streptococcus viridans infections.*—These are not amenable to serum treatment. These organisms are frequently concerned in the ætiology of focal sepsis. When pyorrhœa alveolaris is the cause of focal infection, the material from which the vaccine is prepared is to be taken from the apex of an infected tooth immediately after extraction, and not from pus lying about the neck of the tooth which is always the nidus of secondary infections, erroneously thought to be causative of the condition. The initial dose may well be 5 million cocci, followed at intervals of 7 to 10 days by gradually increasing doses—10, 25, 50 and 100 million cocci. Even larger doses may be profitably given should no "reactions" occur.

Fibrositis, arthritis and allied conditions.—In embarking on the treatment by vaccine therapy it has to be realised that such treatment will be brief or long according to the time the lesions have existed. In this connection, moreover, it should be borne in mind that even if the lesions are not of long standing, the toxæmia leading to those lesions may be of much longer standing than at first suspected.

2. *Staphylococcus Infections.*

Chronic local infections.—These consist of boils, carbuncles, pustular acne, onychia, sycosis, otitis media (sometimes), eczema (sometimes), ciliary blepharitis, suppurating Meibomian cyst and certain discharging sinuses. Furunculosis and certain other staphylococcal infections were the first to be treated systematically by Wright's method of specific inoculation, and, as a class, these infections yield, with care, fairly satisfactory results.

A guarded prognosis must, however, be given in connection with each of the other forms of staphylococcus infection. And in all the cases care must be exercised to see that the general points in treatment are receiving attention. If these be omitted, failures will frequently be met with in those cases in which the infective factor is not very dominant. In acne, for example, it is unlikely that vaccines alone will affect a cure if local measures be omitted. Here, as always, the inoculations must be regarded as adjuncts to the general programme of treatment, not as a substitute for it.

In the case of suppurating wounds or sinuses, vaccine treatment should never be expected to take the place of efficient drainage, which must in all cases be secured in the first instance.

In the matter of *dosage* most workers agree in using a dose of 100 million in beginning the treatment of a straightforward case. If improvement follows,

this is succeeded by doses of 250 to 300 million with intervals of 8 to 10 days. The supplementary use of *toxoid* is sometimes helpful. Relapses are quite common, and require a good deal of careful management. Either the doses are not sufficiently large, or the inoculations are repeated too frequently. Each case must be considered on its merits. In the experience of the writers there is often a tendency to stop the treatment too early. It is often of value to "space" the doses more widely as the treatment proceeds.

In the treatment of aene, a similar plan may be followed, or a mixed vaccine of staphylococcus and the "aene bacillus" employed. In sycosis the response to these doses is only satisfactory if the case is treated early. If it is of some standing, and much induration is present, the vaccine should be tentatively increased to 2000, 5000 and even to 8000 million cocci. The same rule applies to many cases of chronic aene. Once more, let it be urged that it is courting disappointment to neglect necessary methods of treatment when dealing with these chronic skin infections.

It has become customary to employ stock vaccines in the treatment of furunculosis and other staphylococcus infections, and, as staphylococci appear to differ little in the matter of strains, the success of this convention justifies the practice. If, however, success is not attending the treatment, an autogenous vaccine should in all cases be obtained. This is perhaps more important if the infection is due to *S. aureus* than if to *S. albus*.

Acute local infections.—A single dose of vaccine certainly tends to cause an acute boil or carbuncle to abort, but it should be administered early to secure this effect. The dose chosen is usually 1000 million of mixed staphylococci. Care must, of course, be taken to give no dose of this size in the presence of any constitutional symptoms which may indicate a general infection. But a general infection may quite probably be avoided by the above-mentioned prompt treatment. In the case of boils of the external auditory meatus and other very painful situations, the more rapid development and consequent resolution of the lesion following administration of a vaccine are of considerable advantage.

Poisoned fingers and acute abscesses due to staphylococcus infection require much smaller doses. They are best treated by (say) 50 to 100 million cocci, with 3 or 4 days' interval.

ERYSIPELAS

Definition.—An acute specific disease, due to infection of the skin by *Streptococcus pyogenes*, leading to local dermatitis and constitutional symptoms, of which fever and toxæmia are the most prominent.

Ætiological Factors.—Infection by *S. pyogenes* is certainly the essential factor. The more carefully the cases are examined and the patients questioned the more certain it becomes that in the great majority of them some abrasion, it may be very slight, is present in the skin at the site of infection. This abrasion may be an actual wound, whether of a surgical operation or not. More often it is less apparent—a scratch, an insect bite, the chafing of a foot by a badly fitting shoe, etc. Contact by the human hand during the infliction of these slight injuries is not uncommonly a feature in the case.

Bad hygienic conditions seem to contribute to the incidence of the disease, such as defective sanitation and ventilation in public institutions. Formerly

the disease was rife, almost epidemic, in hospitals, and chiefly amongst the surgical patients. During the puerperium a woman is prone to erysipelatous infection.

The disease is said to have a seasonal incidence (January to May), and Newsholme showed that the curves of its prevalence conformed somewhat to those of scarlet fever and acute rheumatism. We do not know, however, the reasons for this.

The disease is more common in women than in men, perhaps because of the puerperal cases. Alcoholism is a great predisposing factor. Gout is another factor rather commonly present.

Symptoms.—There is an incubation period of some 2 to 5 days. The onset is usually abrupt, often with a rigor (or a convulsion in little children) and a sharp rise of temperature—102° to 103° F. In severe cases the patient suffers from malaise, aching pains about the body, and headache. The headache may be so severe as to mislead the observer into thinking there is some cerebral infection (*e.g.* meningitis). Delirium may be present, rendering the doubt still greater. If, as is sometimes the case, the local lesion is not apparent to the patient, or is not discovered on examination, the case may be very obscure indeed. But in the majority of instances there is a feeling of heat, tightness, or pain at the site of infection, leading to the recognition of the dermatitis. The inflammation usually appears during the second day—the skin is red, hot to the hand, slightly raised, with a spreading margin upon which there may be minute vesicles containing clear or turbid fluid. The area spreads rapidly, and becomes cedematous, the degree of this latter effect varying with the situation of the inflammation. If this is the face, the cedema is marked, especially if the eyelids and lips are involved: the whole face may then be greatly swollen and the patient's features scarcely recognisable. On the limbs there is frequently present some degree of lymphangitis—red streaks, more or less continuous, stretching upwards towards the groin or axilla, in which situations the lymph glands are frequently swollen, painful and tender. When the dermatitis is fully developed the vesicles already referred to may become blebs of considerable size.

In less severe cases the constitutional disturbance may be much milder, but so long as the diagnosis is definite the development of serious symptoms must always be regarded as possible, especially if the patient be elderly or debilitated.

The course of the disease varies considerably. If uninterrupted by specific treatment it lasts from 1 to 3 weeks. There is a rare type of *recurring erysipelas* in which the same area of skin is involved again and again. One or other of the lower extremities, or the face, is the common site; in the latter case alcohol is a disposing factor. Though the immediate response to chemotherapy may be satisfactory in this type, drugs do not confer immunity.

Complications.—Albuminuria is not uncommon in all cases in which the temperature is high. Signs of nephritis supervene in not a few severe cases; when this is so the question should arise as to the previous integrity of the kidney. Cedema of the larynx is a rare complication; spread of the inflammation from the face to the orbit is less uncommon, and in this event meningitis is to be feared. Pneumonia sometimes occurs, again in debilitated, elderly or alcoholic subjects. Septicæmia, it may be with a fulminating form of septic endocarditis, is another serious possibility.

Diagnosis.—Reference has already been made to those cases in which the real nature of the disease is masked by the severity of the general invasion symptoms and the non-discovery of the skin lesion. Apart from such instances the diagnosis is rarely difficult if the examination be carefully conducted. The presence of even the smallest vesicle in association with a suspicious red area of skin should be investigated by piercing it with a very fine capillary glass tube and filming and cultivating the contents, even if these seem to the naked eye to be almost clear fluid. The discovery of a long-chained streptococcus in the films not only establishes the diagnosis, it enables the practitioner to adopt prompt measures of treatment.

Prognosis.—The disease is very fatal in infants and in old people. It is dangerous in alcoholics, nephritics and the plethoric gouty type of patient. In all others the outlook is good, especially since the introduction of sulphonamide treatment. But septicaemia is of grave omen, and if associated with endocarditis it is always fatal. Meningitis, following orbital cellulitis and ophthalmia, is scarcely less lethal. The occurrence of acute nephritis, of cellulitis of the neck or of pneumonia, though all of these give rise to great anxiety, does not render the case hopeless.

Treatment.—**PROPHYLACTIC.**—The patient should be isolated, and the greatest care should be taken in nursing, as well as in all the examinations made by the medical attendant. The sick-room should be large and well ventilated.

CURATIVE.—(i) *Local measures.*—Various applications are in use. Perhaps one of the best is ichthammol ointment (25 per cent.), though this has the disadvantage that it somewhat obscures the local signs. A lotion of perchloride of mercury (1 in 4000), continuously applied on linen strips, is free from this objection. The old method of painting the spreading edge of the dermatitis, and the healthy skin around it, with tincture of iodine, has many advocates. In erysipelas of the face the eyes should be protected by a few drops of mild silver protein (argyrol) (5 per cent.) applied two or three times in the 24 hours.

(ii) *General measures.*—Sulphonamide therapy should be employed immediately the disease is diagnosed. (For scheme of dosage, see p. 17.) Full diet is allowed, provided it can be digested. In severe cases ample fluid must be given, as to all "septic" diseases. Volatile stimulants (brandy) are indicated whenever the constitutional symptoms are severe and the heart flags. Febrifuge drugs are best avoided, the temperature being controlled by hydrotherapeutic or arotherapeutic methods.

(iii) *Immune therapy.*—The use of univalent *S. pyogenes* serum, preferably concentrated, and in certain cases the use of "scarlet-fever antitoxin," in combination with sensitised *S. pyogenes* vaccine, should be considered in all cases in which sulphonamide treatment is not proving successful.

(iv) *X-ray treatment* has been successfully exploited.

GONOCOCCUS INFECTION

The *gonococcus* is a small diplococcus, having its two adjacent surfaces flattened or slightly concave, with a small oval interval between them. It is Gram-negative in its staining reaction, and, when seen in exudates and in

tissues, it is very largely intracellular in distribution, and eosinophil cells are commonly present in the pus—helpful features in diagnosis. The gonococcus is a very strict parasite, being dependent for spread upon direct transference from host to host. It probably does not live outside the human body for many hours.

MODES OF INFECTION.—Sexual intercourse is by far the most common and important mode of infection. Contamination of the conjunctival sac of the newborn infant by infected vaginal secretions is another important way by which the organism is transmitted. Least often, accidental contamination sometimes occurs from infected material, either of the vagina in little children or of the eyes in children or adults.

CHARACTERS OF GONOCOCCUS INFECTION.—Perhaps the most peculiar, and certainly the most important, feature of gonococcus infection is its obstinate persistence. This organism is, relatively to many others, responsible for few deaths as the direct result of acute infection, but this low mortality ratio is compensated by a high degree of morbidity incidence. Once the invasion of gonococci has led to definite tissue infection, this is prone to become very intractable, resisting the most persevering and thorough efforts at defeating it. Gonococcus infection is too often measured by years rather than months, though there are oft-times intervals of comparative freedom from toxic effects upon the infected organs. Such a lesion as acute iritis, for example, may appear in the subject of old gonococcus infection, several years after the primary invasion, and the evidence that the inflammation is due to this source may be unimpeachable. The writer has known this to happen fourteen years after the primary urethritis. But it is sometimes very difficult to exclude a recurrence of the initial infection.

Once the inflammatory response to infection has passed the urethral stage, it is often very difficult to obtain direct bacteriological evidence of the nature of a suspected gonococcus infection. The number of organisms concerned may be small, they are often deeply embedded in the tissue spaces and cells, and they may not be shed into any effusions or secretions that chance to be available for clinico-pathological investigation. As yet, the indirect diagnostic methods (agglutination, complement fixation, etc.) are scarcely of sufficient trustworthiness to supply the data left lacking by the negative direct bacteriological results referred to.

Secondary infection, especially by staphylococci, streptococci and diphtheroid organisms is very common.

CLINICAL RESULTS OF GONOCOCCUS INFECTION.—These may be considered under three headings: the results of the primary infection, the results of the zone of immediate spread, and the results of general dissemination.

(i) *The results of the primary infection.*—These are acute and chronic urethritis (with gleet); cervicitis; and conjunctivitis. These lesions do not come under consideration in a text-book of medicine.

(ii) *The results in the zone of immediate spread.*—These include periurethritis (and abscess), prostatitis, epididymitis and vesiculitis in the male; salpingitis with salpingo-ovaritis in the female; and cystitis in both sexes. In both sexes, again, the peritoneum may become infected locally, a much more common and important event in females than in males, as might be expected for anatomical reasons. Indeed, in women, varying grades of pelvic peritonitis, with plastic inflammatory changes, constitute perhaps the

greatest hane of gonococcus infection, both from the physician's and the surgeon's point of view. Chronic ill-health, adhesions that permanently handicap the functions of the pelvic viscera, and acquired sterility are amongst the disabilities accruing therefrom. In the male, late results of infection are scarcely less serious by way of nemesis: urethral stricture, chronic prostatitis, "ascending" pyelitis and secondary coliform infection of the urinary tract.

(iii) *The results of general blood infection.*—These may be subdivided into a true septicæmia and pyæmic manifestations.

(a) *Septicæmia*, though rare, has been definitely established clinically and clinico-pathologically, both in America (Thayer, Blumer, Ahmann) and in England (Horder). Endocarditis, of a progressive and "ulcerating" form, is present in most of the cases, and, though recovery has taken place in one or two known instances, the disease is generally lethal. Diagnosis turns upon the isolation of the organism from the blood stream in a case presenting the clinical features of septicæmia.

(b) *Pyæmic manifestations.*—Of these the most important is *gonorrhœal rheumatism*, with associated arthritis, fibrositis, teno-synovitis and allied lesions (see pp. 1371–1374). Gonorrhœal rheumatism must be considered to be a form of gonococcus pyæmia, at least when seen in its acute and sub-acute types. The organism has been recovered from the affected joints in a large number of the cases, and in a few from the blood stream as well as from the joints. *Spondylitis deformans* has been traced to (old) gonococcus infection in a considerable proportion of cases.

Pericarditis and *pleurisy* have both been described as remote results of gonococcus infection.

Iritis, already referred to, is prone to be of the recurrent type. It is often ascribed to syphilis when it is much more probably of gonorrhœal origin.

Treatment.—In acute infections the use of sulphapyridine has proved very successful. In chronic infections the same remedy should be given a thorough trial, but the results are much less favourable. The bacteriostatic effect of penicillin on sensitive strains of the gonococcus is high. Antigen therapy may be cautiously attempted.

COLIFORM BACILLUS INFECTIONS

Continued and extended observations, made possible by the introduction of newer differential bacteriological methods, have resulted in the recognition of a large and important group of bacilli, called the coliform group, including members which differ as widely in pathogenicity as these two originally described bacteria, but also including the organisms of bacillary dysentery, the paratyphoid organisms, the various bacilli causing "food-poisoning," such as the Aerttrycke bacillus, *B. enteritidis* of Gaertner, *B. suispestifer* and others.

MODES OF INFECTION.—In health, coliform bacilli are confined to the intestine. The modes of infection of parts of the body other than the bowel are at times very apparent, at others obscure. Of any particular tissue there are three possible routes of infection: (1) The *direct* route, that is, by the

immediate transference from the bowel to the infected area; (2) by the *lymphatics*; and (3) by the *blood stream*. In some infections, *e.g.* of the gall-bladder, pericolic tissues, pelvic cellular tissue, etc., the direct route is no doubt the one generally followed. Of the two indirect routes, however, some doubt exists as to the more likely one in certain cases, such as infection of the urinary tract especially; in some instances of this latter important condition it is clear that invasion takes place again, directly, through the urethra. The cystitis which still occasionally follows the use of the Catheter illustrates this; and the greater frequency of coliform bacillus cystitis in little girls than in little boys has been adduced in favour of this route. In the acute pyelitis complicating or following typhoid fever, it is highly probable, though not certain, that infection proceeds via the blood stream to the kidney, and thus to the pelvis. But in those acute primary infections of the urinary tract, which are so common in both sexes, the mode of entry of the bacillus to the kidney pelvis is problematical.

SITES OF INFECTION.—The sites of infection by coliform bacilli are very numerous. Mention will only be made here of those which form the basis of important disease-processes which demand recognition and treatment in practice.

1. The *bowel* itself may be the site of infection. This may take place (a) because the infecting strain of coliform bacillus has absolute pathogenic qualities; or (b) because the virulence of one or more of the usually saprophytic strains is increased; or (c) because the resistance of the mucosa is lowered by chemical or physical changes or by infection by another pathogenic microbe. From one or more of these factors acute or chronic *enteritis*, *entero-colitis*, or *colitis* may ensue. Gaertner bacillus poisoning, the result of eating contaminated food, is an important instance of (a), and perhaps also of (a) combined with (c). Some cases of *cholera nostras* appear to be due to coliform bacillus infection, and probably most sporadic cases of acute colitis. There is no great obscurity attaching to these infective processes. In a consideration of many cases of *chronic colitis*, however, the exact rôle of coliform bacilli is very obscure indeed; and this, even when we exclude a large number of cases of bowel defect to which the name *colitis* should never be applied at all. It is probable that many of the patients said to be suffering from *intestinal intoxication* are in reality the subjects of subinfection by coliform bacilli. But at present our criteria for judging accurately of such a condition are lacking. Mere qualitative bacteriological investigations of the faeces in such cases yield at most presumptive evidence, and quantitative investigations take us very little farther. We await some method of estimating tissue infection by the coliform group more constant than agglutination, which is rarely present in chronic cases, and is, therefore, of little use as a guide.

2. *Gall-bladder sepsis* is closely associated with coliform bacillus infection. It is commonly held that subinfection of the gall-bladder by this microbe is one of the important factors in the evolution of cholelithiasis. However this may be, it is certain that coliform bacilli are frequent infecting agents in *cholecystitis*, both acute and chronic. The fact harmonises with the known frequency of gall-bladder infection during typhoid fever. The association of coliform infection of the urinary tract and of the gall-bladder is of common occurrence, and the removal of a gall-bladder which is the seat

of chronic inflammation may react favourably upon the coincident urinary infection,

3. *Appendix inflammations, diverticulitis, pericolic suppuration* and local peritonitis complicating intestinal conditions, are all of them associated with coliform bacillus infection, and in many instances with this alone.

4. The *urinary tract* is infected with great frequency, with how great frequency we are only now realising, as the result of systematic cultivation of the urine in doubtful cases of the condition, and in obscure cases of illness in which no such condition is at first suspected. It is important to note, however, that the mere presence of coliform bacilli in the urine—it is assumed that catheter specimens only are being dealt with, or that, when this is not the case, there is good evidence that the bacilli actually come from the bladder—does not establish an actual urinary tract infection. *Coliform bacilli* in the urine may signify one of either of the following conditions : (a) The elimination of the bacilli from the body through the kidney, without infection either of this organ or of the urinary tract ; this process is usually of brief duration, and may be intermittent. (b) The excretion of bacilli (with pus) from an infected kidney or from some focus of infection adjacent to the urinary tract (prostate, urethra, pericolic tissues). (c) True infection of the urinary tract (pyelitis, pyelonephritis, cystitis, pyelo-cystitis). (d) Bacilluria.

Concerning (a) and (b) no more need be said in this place, but (c) demands more consideration.

COLIFORM BACILLUS INFECTION OF THE URINARY TRACT.—The cases met with may be conveniently described as falling into three groups.

(i) *Acute cases.*—In the majority of these cases the infection appears to arise in the pelvis of the kidney ; some are undoubtedly vesical in origin ; in not a few it is uncertain where the infection begins. The disease is at times quite fulminating in its acuteness, being ushered in by rigors, high fever (103° to 105°), delirium and great drowsiness. More often the symptoms are abrupt and severe, but not alarming. There may be pain and tenderness in the loin, and one or other kidney may be tender under bimanual examination. But in more cases than not there is a striking absence of both physical signs and focal symptoms, so that, unless the existence of the disease is borne in mind, and the urine is examined carefully, the patient is thought to be suffering from "influenza."

In those cases in which the bladder is, from the first, markedly affected, symptoms of *dysuria* are present—frequency, pain and strangury. Such symptoms draw attention, of course, to the nature of the process.

The *urine* shows a great range of variations in its features. There may be a fairly frank *hæmaturia*, a fact which is not so widely known as it should be : coliform bacillus infection is the explanation of a large number of obscure cases of *hæmaturia*. The amount of pus is very variable—it may be very considerable, or it may be represented only by leucocytes seen on microscopic examination. In very severe cases portions of the bladder mucosa may be shed in the form of sloughs, but this is uncommon. Like the pus, the bacilli vary greatly in the degree to which they are present in the urine ; in some cases they are so abundant as to constitute by far the greater part of the total sediment. The colour and amount of the urine depend upon the

degree of pyrexia and the amount of fluid ingested. Constipation is the rule, the tongue is generally covered by a creamy fur, and anorexia is common. As in so many acute coliform bacillus infections, the mental state tends to depression.

The disease is often a strikingly dramatic one in children; it is one of the few conditions which may be associated with a rigor, and there is a maximum of febrile reaction with lassitude and even stupor, and a minimum of serious effect upon the vital organs. It is not very uncommon to see a temperature of 105° or 106° , with big intermissions; the child is very ill during the pyrexial stage and comparatively well when the temperature falls. Marked drowsiness, even stupor, may occur; such a condition, indeed, should raise a suspicion of this infection in the absence of signs of meningitis. The disease is not very uncommon even in babies.

The course of the disease varies much. Prompt recognition of its nature, leading to appropriate treatment, usually results in defervescence and the disappearance of pus and bacilli from the urine in 7 to 14 days. But some of the cases last many weeks; it is fair to say that this is not seldom due to failure to diagnose the condition, or to employ efficient measures of treatment.

Relapses are very common even when, with chemotherapy, the urine is rendered sterile and the symptoms are relieved. Of *complications*, *prostatitis* is perhaps the one most often seen; *epididymitis* occurs less often, but is a very definite condition; *urethritis* may occur; *pyelonephritis*, especially in young children, may be the precursor of renal failure in later life. It is interesting to record that epididymitis may be the first symptom of the disease. This has, in the past, been frequently mistaken for tuberculosis.

(ii) *Recurrent cases*.—A not uncommon type of case is that in which symptoms of acute or of subacute infection occur at intervals over a number of years, the condition of the patient and of the urine being natural between the attacks. Recurring hæmaturia, thought to be due to acute nephritis, to tuberculosis or to calculus, is sometimes due to this condition. The probable source of these re-infections in any individual case is the colon.

(iii) *Chronic cases*.—These are either (a) the sequelæ to acute attacks that have never completely resolved; or (b) they arise insidiously; or (c) they follow instrumental procedures or operations upon the urinary tract; or (d) they complicate mechanical defects, such as stricture (acquired or congenital), enlarged prostate, and hydronephrosis; or (e) they occur as secondary infections in cases of renal or vesical calculus or of tuberculosis.

The symptoms in these chronic cases vary greatly. In one group it is the general toxic state that is the main feature—a sallow complexion, loss of tone, a low blood pressure, colon dyspepsia, headache and backache. In another group the local symptoms predominate—increased frequency of micturition, which may be extremely trying, pain during or after the act, and referred pain and discomfort in the vesical zone. In a third group there is little or no interference with health, general or local; but a vivid realisation of the existence of the condition troubles the patient's mind, leading sometimes to a state of bladder neurasthenia.

The urine in chronic infections shows as much variety as do the symptoms. The characteristic "fishy" odour is rarely absent; the reaction is generally acid, but infection by *B. proteus* renders the urine strongly alkaline; the amount of pus present may be very little or may be considerable, but the

degree to which the patient is troubled by no means corresponds to the degree of pyuria; mucus is in excess; bacilli are constant and, like the pus, are very variable in quantity. Hematuria is uncommon in chronic infections, but it is easily induced by instrumental investigation, as are also "flares-up," of the chronic state, with the production of rigors, high fever, severe malaise and relative anuria. For this reason, methods of differential diagnosis which do not involve instrumentation should be employed before the patient is subjected to cystoscopy or ureteric catheterisation.

BACILLURIA.—This term is properly applied to a urine which is loaded with bacilli, but in which there is no pus, or, at most, a few leucocytes seen on microscopic examination. It is a state of kidney elimination of bacilli rather than a condition of bacillary infection. It is usually of short duration. The appearance of the urine is characteristic: shimmering when agitated and viewed by transmitted light. The smell already referred to as so typical of colon bacillus urinary infections is usually present here also.

OTHER SITES OF COLIFORM BACILLUS INFECTION.

(i) *The uterus and Fallopian tubes* are sometimes the site of infection, as in puerperal sepsis; but the infection is then usually a mixed one, with streptococci.

(ii) Some situations quite remote from the bowel are now and again infected by coliform bacilli—the *middle ear*, the *pleura*, the *bronchial tract*, *bones and joints*. Infection of the middle ear occurs as the result of impure water in swimming-baths.

B. COLI SEPTICÆMIA, unless it occurs as a terminal event, in which form it is not at all uncommon, is rare. When it does occur, however, it is by no means always fatal. Septic endocarditis, due to coliform bacilli, is rarer still; the only cases coming under the writers' notice have been of the nature of a terminal infection.

Treatment.—The treatment of cases of coliform bacillus infection may be considered under three heads—general, local and specific measures.

1. **GENERAL MEASURES.**—In all acute cases the patient is kept in bed, so as to ensure rest and warmth. Both of these are essential, and even in chronic cases it is of great importance to avoid cold and fatigue. As the *bowel* is the source of nearly all the infections, attention to it is paramount. It is quite impossible to say in how many seemingly unlikely cases the intestine, and especially the colon, will be found to give the clue to treatment, provided the possibility be borne in mind. Especially is this the case in acute and subacute cases. To correct constipation is not enough—constipation may not even be present—efforts must be made to change the bowel contents in such a way that they are no longer so good a nidus for growth of the bacillus. This is best attained by a *diet* which is low in total protein content; meat, eggs and raw milk are excluded entirely; junket, whey, buttermilk and cream being allowed. The following articles of food are also allowed: macaroni, boiled rice, raw and cooked fruit, salads, and lightly cooked green vegetables, jams, marmalade, honey, cold fat bacon and ham, and chicken and white game occasionally. Wholemeal bread and oatmeal porridge are recommended. On such a diet the consistency of the stools soon improves, and they lose their ill-digested appearance; as also mucus and sandy deposit, if these were present. They also become much less offensive to the smell. Plain drinks are encouraged—preferably between

meals. If the case be acute, with considerable pyrexia, the practitioner generally considers milk the staple food indicated; but even in these cases it is often possible to demonstrate rapid progress so soon as milk is disallowed.

The choice of *aperients* is of great importance. In acute cases, calomel is very useful combined with salines. In chronic cases, the most helpful form of laxative is of the paraffin and agar-agar type (emuls. paraff. liq. cum agar., B.P.C.), supplemented if necessary by a compound aloin pill.

A course of *high colonic irrigations*, following the Plombières method, is indicated if mucus persists in the stools despite the above measures.

In acute cases of infection of the urinary tract with high fever and dysuria, full doses of *alkalis* (sod. bicarb. and pot. cit.) combined with tincture of hyoscyamus are helpful for the first 3 or 4 days. Bicarbonate of soda may be added to barley water and citrate of potash to lemonade; the patient is encouraged to drink freely of these fluids, at least 3000 c.c. (4 pints) in the 24 hours. By the time the urine has been strongly alkaline for 3 days the temperature will most likely have fallen: indeed, if the pyrexia persists unabated in such circumstances search should be made for some cause other than a coliform infection of the urinary tract to explain it. An alternative treatment, and one which should be employed in any case not responding to alkalis, is by the usual scheme adopted with sulphonamides. An initial dose of 2 gm., followed by 1 gm., two-hourly by day and four-hourly by night (*i.e.* ten doses totalling 11 gm. in 24 hours). This dosage is maintained for 48-72 hours and then halved for the next 3 days, by which time the urine will probably be sterile. In elderly patients with chronic cystitis the infection may be kept in check with the aid of 0.5 gm. three times a day on four days a week. (For other details of sulphonamide therapy, see pp. 17-18.)

If for any reason it is judged unwise to administer sulphanilamide (sulfanilamide U.S.P.), or if on trial the patient proves intolerant thereof, *mandelic acid* should be tried; with this drug the fluid intake must be restricted. Salts of mandelic acid, such as ammonium mandelate, gm. 3 (grs. 45), given by mouth every 6 hours, diminish the growth of coliform organisms, provided the urine is kept highly acid, that is the pH between 5.0 and 5.5. Acid sodium phosphate, in doses of gm. 2 (grs. 30), should render the urine sufficiently acid; to determine that this is so, to half an inch of urine in a test tube add a few drops of methyl-red solution: the resulting colour should be pink. Each specimen of urine is so tested, and the dose of acid sodium phosphate adjusted accordingly. The treatment may have to be maintained for 7-10 days; recrudescence or recurrence of infection is not infrequent and demands a further course. Mandelic acid therapy is contra-indicated in all cases of renal failure, as the accompanying acidosis may cause a rapid rise in blood urea.

If these measures fail the *hexamine group* will do good in proportion as the infection is focused in the urinary tract and in the renal pelvis rather than in the bladder. To get the greatest service from hexamine in urinary tract infections it is best to keep the urine acid, and for this purpose acid sodium phosphate is serviceable. It is well to change the hexamine (gm. 0.3 to 1.6 or grs. 5 to 25 well diluted) for one or other of its derivatives now and again, reverting to the hexamine again later: hexamine sodium acetate (cystopurin), hexamine with citrate (helmitol), hexyl-resorcinol (caprokol). In chronic cholecystitis much larger amounts of hexamine have been

employed, up to gm. 14 (grs. 200), given in ten equal doses in the 24 hours; it is essential that the reaction of the urine should be maintained alkaline lest hæmaturia and strangury ensue.

2. LOCAL MEASURES.—Local suppurations are, of course, dealt with surgically. Reference has already been made to associated disabilities in some cases of urinary infection which also require surgical treatment. In bowel infections a useful adjunct in treatment is to endeavour by means of posture, massage and efficient supports to improve matters if enteroposis be present.

3. SPECIFIC MEASURES.—There remains to be discussed the use of bacillary vaccines. These should always be regarded as supplemental to, rather than substitutions for, the scheme of therapeutics outlined in (1) and (2). In acute cases vaccines are not indicated. In chronic cases, if vaccines are employed they should be given a good trial; it may be that a streptococcus is associated with *B. coli*, in which case an autogenous vaccine of this organism should also be given. Sometimes the good effects are striking, at others little or nothing is achieved. *The vaccine should invariably be autogenous in nature.*

✓ TUBERCULOSIS

Definition.—Infection of the body by *Bacillus tuberculosis*, leading to lesions which are characterised by tubercles, microscopic or macroscopic, themselves undergoing changes leading to caseation, necrosis, ulceration and calcification, and having in close association with them varying degrees of fibrosis. The lesions of tuberculosis form the histological and anatomical basis of a large number of diseases which differ according to the organs affected, the extent of the lesions and the degree of resistance to infection shown by the tissues.

Ætiology.—THE BACILLUS TUBERCULOSIS (Koch, 1882).—This is regarded by many bacteriologists as a member of the Streptothrix group of micro-organisms; that is to say, the bacillus found in tubercular lesions is considered to be the bacillary form of an organism allied to the Streptothricæ. The other phases in the life-history of the micro-organism are not met with in the actual disease-process, but may be demonstrated in old cultures and in certain experimental lesions. This view of the essential nature of the tubercle bacillus harmonises with our knowledge of its great power of resistance to various destructive agents; it also explains many of the tissue changes occurring in the disease, the latency seen in many cases of infection and the chronicity of many others. The bacillus measures 1·5 to 4 μ in length as an average, is slender, and when isolated from secretions or tissues is usually bent or curved, and tends to lie in small groups. It is “acid-fast” in its staining reactions, allowing of easy recognition; but it grows very slowly outside the body, requiring special media for the purpose of culture. The bacillus is capable of living for several months in dried sputum, and may be cultivated, or may be made to cause disease in susceptible animals, when obtained from the dust of ordinary living-rooms. The gastric juice does not destroy the bacilli, nor does the process of decomposition going on in dead tissues over a period of many weeks. The clinical importance of these facts is obvious. In contrast with these examples of resistance may be mentioned the fact that direct sunlight has a rapid lethal effect

upon the micro-organism; so also has a solution of carbolic acid, of strength 1 : 20.

Known differences exist between the bacillus causing tuberculosis in man, in cattle, and in birds respectively. The *avian* form appears to be of little importance. The *bovine* type would appear to cause about 10 per cent. of all cases of tuberculosis in man. In children, the *bovine* type is found relatively more often. The *human* type of bacillus is less virulent to cattle than is the *bovine* type, but—though this cannot be made the subject of experiment—the *bovine* type is probably as virulent to man as is the *human* type. Of young children dying with primary abdominal tuberculosis, the fatal lesions, in nearly half of all cases, have been referred to the *bovine* bacillus. Again, in both children and adolescents suffering from tuberculous adenitis, a large proportion of the cases examined could be referred to the *bovine* bacillus. Lastly, in lupus, about half of all cases appear to be referable to the *bovine* type of *B. tuberculosis* (Royal Commission on Tuberculosis).

SOURCES OF INFECTION.—There are two great sources of infection of tuberculosis—phthisical sputa and tuberculous milk. Sources of minor importance are urine and faeces containing the bacilli as the result of active lesions in the urinary and intestinal tracts, and the flesh of tuberculous cattle eaten as meat. But the main source of the infecting bacilli of the human type is undoubtedly dried human sputa. Nuttall found that from 2 to 4 billion bacilli were expectorated in 24 hours by a patient whose phthisis was only moderately advanced. These bacilli are scattered freely in dust when the sputa become dried, and they lie about the surface of the patient's body, or they are projected directly into the air along with particles of moisture when patients cough or sneeze or even speak loudly.

Of the *bovine* type of bacillus it is probably not an exaggerated estimate to say that some 25 per cent. of all dairy cows in this country are tuberculous. In New York, Hess found tubercle bacilli in 16 per cent. of the 107 specimens which he examined.

MODES OF ENTRANCE OF THE BACILLUS INTO THE BODY.—Although there are some other channels and modes of entry that have theoretical interest, the two chief ways by which the body is infected are undoubtedly ingestion of the bacilli by the alimentary canal and inhalation of them by the respiratory organs. Compared with these two, all other avenues of infection are trivial.

1. *Ingestion.*—Infection through the *intestinal mucosa* is considered to be the most common mode of production of tuberculosis in children, the main source of the bacilli being contaminated milk. This conclusion has the confirmation of clinical and post-mortem observations, as well as the support of experimental work by Behring, Calmette and others. Ghon has adduced facts which suggest that, even in little children, infection may be much more often brought about by inhalation than was formerly thought. Ghon's observations have been confirmed by Eastwood and Griffith, and by Canti.

Another channel of entry by ingestion is the *tonsils*; tubercle bacilli have been demonstrated by Hugh Walsham and others to pass through the tonsillar tissue to the cervical lymph glands. The tonsils are themselves rarely affected.

2. *Inhalation.*—Primary infection by the route of the air passages is

difficult of proof and, indeed, some authorities regard it as negligible compared with (1). The great frequency of respiratory tuberculous lesions, however, and the incidence and mortality-ratio of pulmonary tuberculosis in ill-ventilated districts and buildings, are points difficult to explain satisfactorily without the assumption that in the majority of these cases infection takes place by inhalation. The sequence of events is considered to be somewhat as follows. Finely divided droplets carrying the bacillus are inspired during childhood. The bacilli are conveyed by the lymphatics to the glands which become inflamed but, later, heal. A few bacilli escape the gland filter and are redistributed by the blood stream in diffuse fashion in the lungs. Foci so produced mostly heal, but those near the apex do so less readily, and come to constitute the lesions of chronic pulmonary tuberculosis.

The statistics relative to contagiousness in tuberculosis institutions are conflicting.

3. *Inheritance*.—Inheritance of tissue-susceptibility to infection by tuberculosis is a definite fact. But inheritance of tuberculosis is problematical, if by this is meant the transmission of tubercle bacilli in the spermatozoon or in the ovum. In the few cases of "congenital tuberculosis" that have been authentically described, the transmission has probably been from a diseased placenta to the blood of the foetus.

4. *Skin inoculation*.—This is of little more than theoretical interest. Post-mortem warts (*Verruca necrogenica*) are occasionally of tuberculous origin. Czerny, the surgeon, reported a couple of cases of inoculation during skin transplantation.

Among other *etiological factors* the chief is undoubtedly the *inherited tissue-susceptibility* to infection already referred to. The exact nature of this susceptibility is not known, but its existence is one of the cardinal facts of clinical medicine. *Sex* seems not to be a factor. *Racial differences* in susceptibility are noticeable, though the distinction between morbidity-incidence and mortality-incidence must be made here—the former is high in the Irish, the latter in negroes. In the Jews, though the disease is common, the mortality-incidence is low. *Trauma* is definitely known to induce pulmonary infection, or, perhaps it should be said, pulmonary spread of the disease. All *occupations* tending to inhalation of dusty particles, and those which keep the workers in ill-ventilated and badly-lighted rooms and places, increase the liability to tuberculosis, especially of the pulmonary kind. If *bad economic conditions* concur with either of these the liability is increased. *Debility*, whether the result of acute illnesses, or caused by pregnancy, parturition, prolonged lactation, or exhausting modes of life generally, increases a natural susceptibility, and gives an acquired susceptibility when no hereditary weakness is present. Tuberculosis is not infrequently a *terminal infection* in such diseases as diabetes, cirrhosis of the liver, leukaemia and chronic nerve affections such as tabes dorsalis, etc. *Recurring and chronic respiratory catarrhs* seem at times to lower the local resistance to tuberculosis, though it is often matter for comment that so many patients with emphysema, asthma and chronic bronchial catarrh live for many years without developing pulmonary tuberculosis, provided they inherit no special tissue tendency to infection by the bacillus.

INCIDENCE AND MORTALITY.—The healthy human body is considered to be relatively immune to infection by the bacillus of tuberculosis. Against

this statement, however, it must be said that, whether from the ubiquity of the causative germ, or from one or more of several factors enumerated in the preceding paragraph, some 70 to 80 per cent. of all adult cadavers carefully examined in Western countries show lesions due to the bacillus. It is said, too, that one-seventh of the whole race dies as the direct result of tuberculosis. The disease is one of "low resistance," this being the result either of inherited predisposition or of acquired loss of resistance, or of both of these.

The results of infection are of great variety and of all grades of intensity. The variety depends upon the tissues affected, and the route of spread of the infection. The intensity depends upon the degree of relative virulence shown by the bacillus, and the amount of resistance shown by the patient. Tuberculosis may exist without appreciable disturbance to health, and the lesions produced may be commensurate almost with the whole length of a patient's life. On the other hand, the infection may cause an illness of the most severe character, killing the patient in a few weeks. The results of infection are described elsewhere in this book under appropriate headings, but *general infection* leading to the condition termed general tuberculosis is included in this article.

Diagnosis.—THE ISOLATION AND RECOGNITION OF THE BACILLUS.—In all doubtful cases of tuberculosis this is a point of vital importance. Clinical evidence of the existence of the disease, however complete it may seem to be, must never lack the confirmation of bacteriological proof, whenever this is possible. ("Physical signs are the signs of conditions, not of diseases.") Seeing that the only radical proof of the existence of the disease is the demonstration of the bacillus in material derived from the patient, attention must first of all be directed to this investigation. By comparison with this demonstration, even the most definite "reaction" to one or other of the tuberculin tests, or the most strikingly positive result with the complement-fixation method, is untrustworthy. It behoves the practitioner, therefore, to watch jealously for any material that may be available for bacteriological use, and to be quite certain that such material is not obtainable before falling back upon indirect clinico-pathological evidence (see below) to support the diagnosis.

In cases of suspected phthisis, every effort must be made to secure sputa, and it may be necessary to check a habit of swallowing expectorated material. The single, isolated plug of mucus, which is often expectorated in the early morning, should not escape attention. In little children, sputa, as such, are usually absent, but if vomiting occurs in association with lung disease the vomit should be searched for fragments of sputa. In suspected disease of the kidney or urinary tract, the urine must be collected for 24 hours and the deposit submitted to examination. Cases of *albuminuria* or of *hematuria*, in which there is not clear evidence of diffuse nephritis, should raise the question of tuberculous disease of the kidney. Stomach washings, withdrawn first thing in the morning, and the feces should be scrutinised in doubtful cases of tuberculosis of the lung, peritoneum or bowel. If any *puncture-fluid* is obtainable—as from the pleura, the spinal theca, or a joint—this is valuable for investigation in any patient suspected of tuberculosis.

The methods of dealing with these materials are not difficult, though they require thoroughness and patience when the bacilli are present in scanty

numbers. The very different significance to be attached to a positive as against a negative result must never be lost sight of; the former affords proof of the existence of a tuberculous lesion, the latter gives at most a presumptive evidence against it.

In dealing with *sputa*, the original carbol-fuchsin method of Ziehl-Neelsen should first be tried. If the results, after carefully searching 3 or 4 films for half an hour, are negative, the sputa should be shaken up thoroughly with ten times its bulk of carbolic acid, of strength 1 : 20, allowed to sediment, the supernatant fluid run off, and films made of the residue. If the sputa are seen to be thin and watery, this method is likely to give a negative result. If so, one of the digestion methods may be used—either pepsin and hydrochloric acid, or “anti-formin.” The use of the last-named substance, consisting of a mixture of equal parts of bleaching powder solution and a 15 per cent. solution of caustic soda, is found by some workers to give excellent results. An amount of this fluid, equivalent to about one-fifth of the bulk of the sputum, is mixed with it, allowed to act for 3 to 4 hours, the mixture centrifuged, and the deposit dealt with by one of the staining methods in ordinary use. The bacilli are, by the disintegrating action of the “anti-formin,” isolated from the albuminous vehicle and concentrated in the deposit.

Sediment from urine is best dealt with by the carbolic acid method (*v.s.*), subsequent centrifugalisation, and staining of the deposit. The smegma bacillus (also acid-fast), which may be present if the specimen has not been obtained by catheter, is differentiated by allowing the stained films to remain in alcohol for 10 minutes; the tubercle bacillus is not decolorised. In *pus*, the search is much facilitated by the use of “anti-formin,” and this is a useful adjunct in the examination of *feces* also. A patient suspected of tuberculosis of the bowel often suffers from diarrhoea; when this is the case, Emery's suggestion of giving sufficient opium to cause a solid stool is useful. The superficial parts of the motion are most likely to yield the bacillus, and are chosen accordingly; considerable experience is required on the part of the pathologist, for all acid-fast rods found in *feces* are not necessarily tubercle bacilli.

Puncture-fluids very frequently give negative results to ordinary microscopic examination, on account of the scantiness of the bacilli in them. However, the clot (if such occur), or the centrifuged deposit, should always be searched thoroughly, as the demonstration of even a few bacilli of undoubted morphological characters is decisive. Cerebro-spinal fluid should be incubated, without shaking, for 24 hours, and the “spider-web” clot stained for bacilli. Failing this demonstration, the fluid should be used for culture on Lowenstein's medium (growth takes 3 weeks), and for inoculation purposes, a guinea-pig receiving a liberal amount (not less than 10 c.c. if possible). The inoculation method of diagnosis is, of course, available for the above materials also, as a final test.

The demonstration of tubercle bacilli in the *blood* has received attention of late years, but with widely different results in different hands. Reputable authorities state that bacilli can be seen in stained films in a very high percentage of all cases of tuberculosis, wherever the lesion may be. Others fail to confirm these results.

Indirect Methods of Diagnosis.—These depend upon the presence in the tissues of certain sensitising and immunising substances. They are indi-

cated in doubtful cases of tuberculosis in which no material is available for investigation by direct methods (see above). The relative values of these methods are still under assessment; at present their values are probably in the order of their description here.

1. **THE TUBERCULIN TEST.**—The test depends upon the fact that infection by the tubercle bacillus renders the tissues supersensitive to the toxins of the bacillus, if these be introduced into it artificially. This supersensitiveness is shown by the production of certain "reactions" which are recognisable and are regarded as more or less "specific" in their nature. The test is performed in three ways.

(a) *The subcutaneous test.*—The use of "old tuberculin" by this route (Koch's test) is not without danger, and has been superseded in human practice by other methods.

(b) *The skin test (Pirquet's test).*—This is best employed quantitatively. Three or more strengths (e.g. 25, 50 and 100 per cent.) of a solution of old tuberculin are rubbed lightly into the skin of the arm, which has been previously scarified. The appearance of papules and erythema at the site of vaccination constitutes a positive reaction.

A modification is the Vollmer patch test introduced in 1937; or a jelly containing old tuberculin 95 per cent. may be applied, as recommended by Paterson, to a small area of skin between the shoulder blades previously cleansed with acetone. The area is covered immediately with a piece of elastoplast, which is left *in situ* for 48 hours. A positive reaction is shown by erythema or slight vesiculation.

(c) *The eye test (Calmette's test).*—This test is now seldom used.

(d) *The intradermal test (Mantoux).*—0.1 c.c. of 1 in 1000 and of 1 in 10,000 old tuberculin are injected into the cutis. Redness and cedema, appearing within a few hours and reaching a maximum on the following day, constitute a positive reaction. The test is an extremely delicate one and this fact restricts its clinical value.

(e) The erythrocyte-sedimentation rate is increased in all cases of active tuberculosis, but not only in this disease.

2. **THE COMPLEMENT-FIXATION TEST.**—This test is analogous to the Wassermann test for syphilis. It is claimed by some workers that it is positive in over 90 per cent. of cases of tuberculosis. The difficulty seems to be that it cannot be relied upon to distinguish an active lesion from one that is not active. Seeing that old and caseous tuberculous lesions exist in such a large proportion of all persons likely to be tested, and that these old lesions still suffice to give the complement-fixation test, its value is quite doubtful unless undertaken in a quantitative manner.

3. **THE TUBERCULO-OPSONIC INDEX.**—This is now only of historical interest.

4. **CYTOLOGICAL EVIDENCE OF TUBERCULOSIS.**—Another, and very useful, evidence of tuberculous infection is to be obtained in cases of pleural, peritoneal and meningeal exudates, by estimating the relative numbers of polymorphonuclear cells and of lymphocytes. It is found that, in pure tuberculous infections, the cell exudate is largely, and often almost entirely, lymphocytic in character. In pyogenic infections it is very largely polymorphonuclear; in mixed infections (tubercle with pyogenic infection) the cell-exudate is also of a mixed character (Widal and Ravaut).

5. A FALL IN CHLORIDES IN THE CEREBRO-SPINAL FLUID.—In tuberculous meningitis a fall in chlorides in the cerebro-spinal fluid below 650 mgm. per cent. is pathognomonic of that disease.

Treatment.—This is prophylactic and curative.

1. **PROPHYLACTIC.**—The widest possible view should be taken of the preventive measures which are necessary in order to stamp out the disease. If, as seems certain, the three dominant factors in the persistence of the disease are—(i) the inherited tissue-susceptibility; (ii) the bacillus; and (iii) bad hygienic and economic conditions of life, it is clear that the problem is not a simple one.

(i) Families having an inherited tendency to tuberculosis should recognise the fact earlier and more thoroughly than is usually the case. The upbringing of the children needs special care, and occupations should be chosen for them when they reach puberty which keep them in the open air. Climatic considerations are also of importance in the case of these families.

(ii) As already stated, the two great sources of the tubercle bacillus are the sputa from infected pulmonary cases and tuberculous milk. The former of these is both a public and a private concern—the latter is almost entirely public. Pasteurisation is an effective safeguard.

(iii) This resolves itself into a series of sociological questions.

2. **CURATIVE.**—*Non-specific measures.*—These consist in efforts at improving the patient's nutrition so as to increase the tissue-resistance to the infection—ample fresh air, plenty of good food, bodily and mental rest and exercise undertaken in graduated fashion under expert supervision. Details of all these measures are given in the article dealing with pulmonary tuberculosis (p. 1227).

Specific measures.—With two exceptions tubercular sera and vaccines are of historical interest only. These exceptions are (a) Koch's Tuberculin; (b) Bacille Calmette-Guérin (B.C.-G.).

(a) *Tuberculin.*—This is used most for urogenital tuberculosis. (Doses as in text.)

(b) *B.C.-G. (Bacille Calmette-Guérin).*—This is a "live" vaccine prepared from a strain of tubercle bacillus which has been so attenuated that it has lost much of its capacity for producing disease.

It has been widely used in France for prophylaxis. Three doses of living bacilli are given by mouth to infants during the first 10 days after birth, before natural infection has occurred.

About 100,000 infants in France, mainly those born of tuberculous parents, have been treated. It is too early to assess the results, but there is one great objection to the method, i.e. the possibility that the organism itself may be capable of regaining virulence in the human body.

Chemo-therapy.—A number of substances have been used from time to time. The most recent, and perhaps the most successful, is Sanocrysin. (See p. 1230.)

GENERAL TUBERCULOSIS

Synonym.—Acute Miliary Tuberculosis.

Definition.—A disseminate form of tuberculosis, giving rise to a very severe and fatal disease analogous to the septicæmias in pyogenic infection.

There are three clinical forms of the disease, according as the symptoms are chiefly referable to the lungs (the *pulmonary form*), or to the brain (the *meningitic form*), or are those of a general infection without focal signs. This latter form is often termed the *typhoid form*. The pulmonary form is described in the section dealing with pulmonary tuberculosis. The meningitic form is described in the section on meningitis.

Symptoms.—The *general* or *typhoid form* resembles typhoid fever very closely. There is usually a period of vague ill-health—as there is in typhoid fever—preceding the more severe illness. When the latter develops there is headache, insomnia, a soft but frequent pulse, rapid respirations, a dry tongue, slight cyanotic flush and pyrexia, which is usually less continued in character than in typhoid fever. Not infrequently the temperature curve is that of a quotidian intermittent fever. In a few cases the rise of temperature takes place in the morning instead of in the evening, a feature not infrequently seen in other pyrexias of tuberculous origin, though not confined to these. Progressive loss of flesh takes place, and also anæmia, but this latter condition may only be found by blood examination, the dusky flush of the face often masking the blood state on mere clinical examination. Towards the end of the illness, suspicious signs of one or other of the more focal manifestations of the infection often arise: copious fine râles over the lungs, tumidity of the abdomen with palpable enlargement of the spleen and liver, or cerebral symptoms suggestive of meningitic involvement. In a suspected case the chest should be examined radiologically, since the suggestive “snow-storm” appearance may be present if general tuberculosis has existed for more than ten days or so.

Diagnosis.—As the term “typhoid form” suggests, the disease resembling general tuberculosis most closely is typhoid fever. During the first week, or even during the first two weeks, diagnosis may be very difficult. In favour of typhoid fever are the persistence of headache, the presence of epistaxis, relative infrequency of the pulse-rate, diarrhoea and early tumidity of the abdomen. In favour of tuberculosis are a frequent pulse-rate, early cyanosis and intermission in the temperature curve. There is leucopenia in both diseases. A positive blood culture occurs during the first week in most typhoid cases, and agglutination with the patient’s serum may reasonably be expected after the end of the first week.

Course and Prognosis.—The disease is invariably fatal, and usually within a period of 6 weeks from the onset of fever and symptoms directly referable to the disseminate infection. A few cases last as long as the eighth week, and one of the writers (H.) has seen a well-authenticated case in which the patient lived until the middle of the tenth week.

Treatment.—This is entirely palliative, there being no specific measures at present known to check the progressive nature of the infection, or to avert its lethal issue.

CEREBRO-SPINAL FEVER

Synonyms.—The name here chosen seems least open to objection. “Cerebro-spinal meningitis” is the best alternative, but cerebro-spinal meningitis may be caused by other micro-organisms than the meningococcus, and meningitis may not be present at all, or may not constitute the chief

lesion, in some cases of meningococcus infection. "Epidemic cerebro-spinal meningitis" is much less desirable, because it suggests that there is an essential difference between the epidemic and the sporadic cases of meningococcus infection, which difference does not in fact exist. "Meningococcus infection" brings the various pathogenic possibilities of the micro-organism into line with those of the pneumococcus, with which it has close analogies, but the term does not connote a disease.

Definition.—A specific disease, due to infection of the body by the meningococcus, occurring both in epidemic and in sporadic form, and most often manifesting itself as an acute meningitis tending to involve the whole cerebro-spinal axis.

Epidemics of cerebro-spinal fever are marked by several features peculiar to the disease, offering a striking contrast with other epidemic diseases. For a long time these features were very difficult of explanation, until the existence of "carriers" became recognised, and supplied the solution to much of the epidemiological problem. Amongst these curious features may be mentioned the erratic nature of the outbreaks, the inability to trace the connection between one epidemic and another, the relative or even total escape of certain localities close to others in which the disease was rife, and the small proportion of persons affected in any one district. In closed communities, such as camps, and especially in times of war, the disease finds a fertile soil. When the "carrier rate" rises above 20 per cent. an epidemic is likely to ensue.

On clinical, bacteriological and epidemiological grounds there is no distinction to be drawn between sporadic and epidemic cases of cerebro-spinal fever. But it is not entirely by means of the sporadic cases that the infecting agent persists, but by "carriers" also. There is little doubt, however, that from the sporadic cases, as from a smouldering infection, new epidemics light up. The present conception of the disease, from an epidemiological point of view, is that of a very widespread infection, with a total morbidity that is very low, but with foci of more intense virulence here and there. These foci of more intense virulence appear and disappear, being preceded and followed by a somewhat higher level of permanent incidence in the districts concerned.

Ætiology.—The geographical distribution of the disease is very wide—world-wide, in fact. A certain affinity is shown for the north temperate zone.

Epidemic cerebro-spinal meningitis is a disease of winter and spring. This seasonal incidence is borne out by all observers, and is a very important feature of the disease. It compares markedly with the seasonal incidence of poliomyelitis epidemics, which are at their height in the summer months.

The question whether cerebro-spinal fever is contagious or not has been a matter of much dispute. The facts would appear to indicate that the disease is contagious, but that the degree to which it is so is very slight. The proofs of the contagiousness of the disease are, briefly, these—(1) the occasional transmission of the disease to doctors and nurses; (2) the occurrence of a succession of cases in one family and in the same house; (3) the importation of the disease into a new country or locality; (4) the mode of spread in any locality; (5) the immunity enjoyed by collections of persons living under the same conditions as those affected by the disease, but unable for some reason to come into contact with them (Netter and Debré). Although direct con-

tagion is uncommon, plenty of authentic instances of its occurrence have been reported.

THE MENINGOCOCCUS.—The meningococcus (*Diplococcus meningitidis intracellularis* of Weichselbaum) is rather smaller than the *M. catarrhalis* and larger than the gonococcus—the other two pathogenic diplococci which are Gram-negative in staining reaction. It is a strict aerobe, and requires the addition of some animal protein or of legumin to ordinary culture media to ensure growth. After cultivation for three or four generations it will grow on ordinary agar, but sub-cultures die rather suddenly. Optimum growth takes place at 36° to 37° C., and growth ceases at 42° C. and at 25° C. Vitality is low, especially to drying; sunlight kills in less than 12 hours.

Types of the Meningococcus.—By employing the agglutination test, controlled by the absorption test, M. H. Gordon has differentiated four separate types of meningococci occurring in the cerebro-spinal fluid of actual cases.

IMMUNE SERA.—These were proved by Jochmann and by Flexner to possess potent immune substances when prepared from the horse by the usual technique. The great advance of past years has been the preparation of type-sera, following Gordon's researches. By the use of these the results of serum treatment, previously somewhat disappointing in this country, proved to be more successful, but it has been largely superseded by chemotherapy.

The primary habitat of the meningococcus, both in actual cases of the disease and in "carriers," is the upper part of the naso-pharynx and the posterior nares.

Symptoms and Course.—Cerebro-spinal fever is protean in its features and especially in its modes of onset. Out of the large number of different manifestations that occur, certain cases repeat themselves with sufficient constancy to constitute clinical "types," capable of description and of recognition.

1. **THE ORDINARY OR ACUTE TYPE.**—The incubation period is difficult to estimate with accuracy; there are reasons for considering it to be 4 or 5 days. The illness begins with the usual symptoms of an acute specific fever, and for the first day or two, or for longer than this if the possibility of the disease under consideration is not borne in mind so as to lead to a special examination, there may be nothing to distinguish the illness from one or other of several acute febrile infections.

The onset is usually sudden, with fever, headache, general malaise and vomiting. The temperature usually rises rapidly and attains a fairly high degree on the first day (102° to 104°).

The headache is usually very intense, is often referred to the occiput, and shows little or no response to the customary palliative drugs given to relieve it.

There is frequently a rigor in the adult, or a convulsion in the infant or child. Vomiting is more often met with in children than in infants, and is quite common in young adults.

In addition to the three cardinal symptoms at the onset—headache, fever and vomiting—the following are quite common, but are not nearly so constant: delirium, pains in the neck and limbs, and some degree of catarrh either of the nose, naso-pharynx, conjunctiva, or ear. In some cases there is considerable bronchial catarrh and in others definite enteritis. In addition to

the pains referred to the limbs there may be pain and swelling of the joints.

After some 2 to 4 days of these initial symptoms evidence of meningeal irritation begins to show itself in more or fewer of the following developments. The vomiting is repeated, despite the fact that the invasion symptoms are past. The pulse is irregular in rhythm, and in older children and in adults it is often relatively infrequent when compared with the height of the temperature. The respirations are irregular. The vasomotor system is unstable, leading to periodic flushing of the face and to the presence of *tâches cérébrales*. The patient lies on his side with legs drawn up and prefers the shelter of the bed-clothes. The pupils are dilated and the light reflex is sluggish. There is photophobia, with intolerance of noise and of all kinds of interference. Examination of the neck reveals a stiffness of the muscles, which cannot be overcome without pain. The hamstrings are found to be taut, so that the knees cannot readily be extended if the hips are flexed (Kernig's sign). The abdomen is retracted and the superficial reflexes are abolished. The mental state is one of restlessness and mild delirium with troublesome insomnia. The headache may become quite intolerable and may require morphine for its reduction. In a considerable number of cases a rash appears during the first week—either a number of large rose spots about the trunk and limbs, or a macular eruption like that of measles or a few small petechiæ scattered over the trunk, neck and extremities. Herpes is common, and is generally situated at the usual places—the angle of the mouth, the chin and the nose. There is a leucocytosis of considerable degree (20,000 to 40,000).

Towards the end of the first week the mental state changes to a condition which may perhaps best be described as one of resistant stupor: the patient can be roused by an effort at examination, or by a change of position; but either proceeding is resented, and he quickly resumes his huddled posture. The headache is less constantly severe, but shows sudden and marked exacerbations, often nocturnal, with complete insomnia. The neck rigidity increases, and the head is retracted. The back also becomes stiff. Flesh is lost rapidly. Polyuria is common, with polydipsia. The temperature generally remains fairly high, and, although this is by no means invariable, the fever approximates to the continued type.

Assuming that the course of the disease is not interrupted by lumbar puncture or by specific therapy, the condition of the patient remains much the same during the second, and perhaps during the third, week of the illness. But the wasting continues. The temperature often becomes intermittent in type. One of the three modes of termination will be followed.

(a) *Recovery*.—This is gradual when it occurs, and is often interrupted by sudden recrudescences, throwing the patient back into a state which leads to renewed anxiety. The temperature chart is often interrupted in its deservescence by sudden rises, with or without a corresponding recrudescence of the meningitic symptoms. Ultimately the fever completely subsides, the patient ceases losing flesh, the headache and stupor pass off, and the rigidities slowly disappear. The pulse-rate remains high for some time in a good number of cases, and some authors regard this as a sign that the patient is not yet free from the possibility of relapse, and therefore as an indication for caution in treatment. The actual stage of convalescence, once it i

established, is rarely interrupted. If the temperature and pulse-rate have remained normal for fourteen days, the risk of relapse may be considered to be passed. It may be some weeks, however, before the patient is free from stiffness.

(b) *Death*.—The ordinary type of the disease is not often fatal during the first 2 weeks. When it is, the stupor passes into true coma, the pulse and respiration rise in frequency, and the temperature often shows a sudden ante-mortem rise.

(c) *Becoming chronic*.—More often, if the ordinary type terminates fatally, it is by passing into a subacute or chronic stage. If the "crises" already referred to continue, or if, despite the fall of temperature, there is no corresponding improvement in the general condition, a state of progressive emaciation supervenes, with a tendency to chronic hydrocephalus. The wasting is sometimes extreme, so that bedsores are unavoidable. The rigidity becomes marked, and approaches, even in adults, that degree termed cervical opisthotonos in infants. Feeding becomes difficult, and this adds to the wasting due to trophic disturbances. The sphincters usually relax, leading to incontinence. Papilloedema develops. The patient may continue in this unsatisfactory state for several weeks, or even months, and yet may eventually recover, and without any residual defects. More often, however, he gradually succumbs to the disease, or, if he eventually survives its ravages, it is to be left with mental defect, deafness, blindness, hemiplegia, or diplegia.

Opinions differ as to the frequency of true relapses in cerebro-spinal fever. This is probably due to the fact that what some authorities term relapses others consider to be merely recrudescences. It is certain that the latter are very common; indeed, they are a characteristic feature of the disease.

2. *THE SUPERACUTE TYPE*.—This form of the disease is common at the height of an epidemic. The invasion symptoms are abrupt, and the patient is from the first very ill. Delirium is marked, with most tiresome insomnia, and the headache may drive the patient to a state of acute mania. The temperature is usually very high (104° to 106°), and intermits. Skin eruptions are more constantly present than in the ordinary type; but are by no means necessarily petechial in character. Discharges are apt to occur from the nose and conjunctival sac. The tongue is dry and tremulous. The meningococcus can generally be grown from the blood by culture, and has even been demonstrated in cover-slip preparations made from the blood direct. The leucocytosis is high (30,000 to 40,000). After 3 or 4 days the active mental state changes to stupor; if the cerebral pressure is not now relieved by lumbar puncture this stupor passes into coma. Even if the pressure is relieved by this procedure there is a great tendency for the patient to slip back into a comatose state; then, with pulse, respirations and temperature all rising, with insensitive pupils and absence of corneal reflex, the surface of the body becomes livid, the lungs congested, and death occurs.

3. *THE FULMINATING OR MALIGNANT TYPE*.—This form is prone to occur during the evolution of an epidemic. But it is by no means rare as a sporadic manifestation of the disease. It is more often seen in older children, adolescents, and adults than in infants and younger children. The abrupt appearance of fever, headache and active delirium, rapidly passing into coma, and the whole course of the disease may not exceed 12 hours.

In all fulminating cases of cerebro-spinal fever there is a rapid development of septicæmia. In some of them the septicæmia covers the whole of the disease, symptoms of meningitis being absent, and the meninges being free from gross lesions on examination post mortem. The patient is most often a child, and a hæmorrhagic suprarrenal lesion is often present. Even more constantly than in the superacute type is a blood culture positive; but the course of the disease is too rapid to admit of a diagnosis by this method during life.

4. MILD TYPES.—These cases are said to be common during the decline of an epidemic. It is at present quite impossible to say with what frequency they occur, because it is certain that many of them are overlooked. They are often treated as cases of "influenza," owing to the resemblance they bear to that disease. Many cases of acute fever with headache and pains in the back and limbs are regarded as "influenza" from a diagnosis by exclusion. They are not subjected to a lumbar puncture because the condition does not seem sufficiently grave. And if they recover from an illness of a few days' duration this is thought to be confirmatory of the diagnosis. In the presence of an epidemic of cerebro-spinal fever, however, a very close scrutiny of these cases should be made, and if there is even doubtful neck-rigidity or Kernig's sign, the cerebro-spinal fluid should be examined. Even when lumbar puncture is not at first decided upon a swab from the nasopharynx should be investigated for the meningococcus.

During an epidemic a patient who presents the symptom-complex of headache, malaise, pains in the back and limbs, slight fever, and some stiffness of the neck is probably suffering from a mild grade of meningococcus infection, and should be treated as such, by a lumbar puncture and the administration of sulphonamide. Subsequent measures will be determined by (a) the course of the disease; (b) the result of the examination of the cerebro-spinal fluid; and (c) the result of the examination of the naso-pharyngeal swab. The value of these cautionary measures is sometimes made apparent by the patient becoming rather suddenly worse after a few days, when it may be quite obvious that the nature of the disease is what was originally suspected.

5. CHRONIC SEPTICÆMIA WITHOUT MENINGEAL SYMPTOMS.—Attention has been drawn to this group of cases in which there is the association of a general blood infection, with bouts of pyrexia, often arthralgia or arthritis and various lesions in the skin: petechiæ, maculo-papular eruptions or subcutaneous nodules.

6. POST-BASIC MENINGITIS OF INFANTS (CERVICAL OPISTHOTONOS OF INFANTS).—These cases were first described (1878) by Gee and Barlow. These observers recognised that they were dealing with a specific disease which had no causative association with tuberculosis, syphilis, or rickets. At the time of these authors' observations no epidemic of this type of meningitis had been described, and the cases were thought, even by later writers, to be met with in sporadic fashion only. It has, however, been recognised that this clinical manifestation of meningococcus infection may occur in epidemics. The post-basic type has been less frequent in this country in recent years.

The characters of the micro-organisms present in these cases were originally thought by some workers to differ from those of the micro-organisms found in the neuter cases occurring in epidemics. This distinction has disappeared of late, and there is more or less consensus of opinion that

although the strain may vary, the causative diplococcus is essentially the same in the acute as in the chronic, and in the epidemic as in the sporadic cases.

Seeing that the clinical features, again, do not differ materially in this type of meningitis from those often seen in cases occurring in older children, and occasionally even in adults, nor from those often seen in infants at times of an epidemic, it follows from these considerations that the inclusion of cases of post-basic meningitis in a general account of cerebro-spinal fever is amply justified.

Post-basic meningitis occurs chiefly in infants between the ages of 6 months and 2½ years. The same type of the disease may, however, be seen in children up to the age of 4 or 5 years. The onset is usually sudden, with a convulsion in many cases, and very frequently vomiting. The temperature rises abruptly, but does not, as a rule, remain high. In most cases the fever has become slight, or is absent, by the end of the first week of the illness. A large number of the patients suffering from the disease are therefore without fever when they come under observation.

The main and characteristic sign of the disease, the retraction of the head, becomes marked about the third or fourth day. It usually persists with increasing severity, throughout the whole course of the disease. With it the back becomes arched, so that in extreme instances the occiput and the sacrum may meet. The extremities are usually in a condition resembling tetany, the stiffness being persistent rather than paroxysmal. Progressive wasting is another constant feature, and the degree of emaciation is often very considerable and very rapid. Of the other symptoms vomiting is one of the most common, and may be very troublesome. The pulse and respirations are usually frequent, and may be irregular.

The disease in most cases quickly enters upon a chronic course. The infant lies motionless in its characteristic attitude for hours at a time, but is not usually comatose. Feeding is not as a rule difficult. The pupils are fully dilated. Blindness is present sooner or later in 30 per cent. of the cases (Langmead), the origin of the condition being central, since papilloedema of any magnitude is quite uncommon. Blindness is rare in the cerebro-spinal meningitis of older children and adults.

Lumbar puncture yields similar results to those found in the ordinary type of the disease; but, as the condition progresses, it is found that the meningococcus fails to appear in the fluid, and the polymorphonuclear cell-content changes to lymphocytosis, indicating the chronic stage of the infection. Dry punctures are not uncommon, indicating the probable closure of the foramen of Magendie by the plastic exudate at the region of the bulb and fourth ventricle. Fluid removed from the ventricles during life, or the examination of fluid found in the ventricles post mortem at this stage, often reveals the meningococcus, showing that the disease is still, in its chronic phase, to be regarded as a persisting infection. Indeed, *the post-basic meningitis of infants is probably to be considered as a meningococcus infection of the pia-arachnoid system with a special tendency to involve the cerebral ventricles by ependymitis.* The peculiar symptoms and course of the disease are thus explained.

Owing to the early development of hydrocephalus in this type of the disease, and the elastic nature of the infant's skull, the head enlarges in all

directions, with bulging of the fontanelles and opening of the sutures between the bones. The shape of the skull thus approximates to that of congenital hydrocephalus. The eyes are turned downwards, and the sclerotics above the cornea are exposed by retraction of the upper lid. If this condition of acquired hydrocephalus has lasted for some weeks, there may be enlargement of the superficial veins about the nose and orbits, and running over the temporal regions to the vertex.

The mortality in this type of the disease is very high, probably over 80 per cent. Some of the cases linger for many weeks, and a few very gradually recover, with, all too often, residual blindness and also perhaps deafness. But the majority succumb to the intracranial pressure effects produced by the distended ventricles, in from 4 to 6 weeks from the onset of the disease.

Complications.—1. *Hydrocephalus* may arise soon after the onset of the disease, or it may develop, and often rather suddenly, during its course, or it may be the final anatomical expression of the infective process, the counterpart of the symptom-complex seen in the chronic state of the disease. Certain symptoms are specially suggestive of the condition: pallor, cyanosis, increased frequency of the pulse with diminution in its tension and volume, shallow respirations, and stupor or coma supervening rather suddenly upon a previous state of consciousness.

If hydrocephalus arise at a later period of the disease than the end of the first week it may show itself with surprising suddenness, and sometimes in patients who seem to have been improving satisfactorily. In addition, to the symptoms just enumerated, there is a recrudescence of the headache, vomiting and fever, which may have to a large extent subsided. More often it appears gradually and concomitantly with the progressive cachexia of the chronic type of infection. A valuable sign of its presence in children and adults is the presence of a resonant note to percussion over the anterior horn of the lateral ventricle (Macewen). This sign is best obtained by placing the head in an upright position and inclining it to one side. The sign is not present in infants in whom the fontanelles are still open.

Hydrocephalus of the chronic stage of the disease is seen very constantly in infants suffering from the post-basic type of infection. Emaciation is a constant feature. The child lies for hours without stirring. There may be reiterated automatic acts, such as the biting of nails or the loosening and pulling out of teeth. The patients are rarely comatose. Vomiting and convulsions may occur.

2. *Psychic Disturbances.*—These are not very common, if the delirium and stupor are excluded. But the delirium may develop into mania, urged thereto by the violence of the headache. During convalescence it is not very uncommon to observe temperamental changes, such as puerility or emotionalism, which rarely persist for very long. Secondary dementia is, however, not unknown.

3. *Motor Defects.*—Cranial nerve palsies are very uncommon. There are three groups of paralytic complications, but none of them is common.

(a) *Hemiplegia* and, less often, *monoplegia* of cortical type. This usually appears at the height of the disease, and is generally of temporary duration.

(b) *Flaccid paralysis* localised to one extremity or to a part of one extremity. The tendon-jerks are lost. Muscular atrophy may ensue, and R.D.

may develop. The prognosis for the limb is by no means bad, and complete, or almost complete, recovery is probable.

(c) *Spastic ataxia*.—It is not uncommon to find convalescent patients very unsteady on their legs when they first begin to walk. Little children often refuse to walk at all for a time, even if they had learnt to do so before the illness began. Older children sprawl about the floor. Adults tend to topple over in an indiscriminate manner. In the majority of these cases there are no signs of organic disease, and the return to a normal gait is usually only a matter of time. In a few of the cases, however, the ataxia is accompanied by exaggerated knee-jerks, true ankle-clonus and extensor plantar response: a state of spasticity. The sphincters are intact, and there is no anæsthesia or analgesia. According to Sophian, who drew attention to these cases, the pupils often remain dilated, with a sluggish light reflex. Recovery, though slow, is the rule.

4. *Special Senses*.—Complications involving the eye are very variable, and yet, in relation to the essentially nervous character if the main lesions of the disease, they are not very common. Fortunately, with the single exception of that form of blindness so often seen in the recovered cases of the post-basic type of the disease, very few if the eye complications are permanent. Inflammatory lesions include conjunctivitis, keratitis, iridocyclitis and (rarely) cellulitis of the orbit. Nervous lesions include extrinsic ocular defects which are not uncommon, but are generally transitory (*i.e.* spasmodic). Amaurosis is relatively common in the post-basic infection of infants; it is fortunately unusual in the more acute infection of children and adults. It is in most cases unaccompanied by any changes in the optic disc, and is therefore to be attributed to cortical changes associated with hydrocephalus. In some cases, however, a state of secondary optic atrophy is present. Optic neuritis is not a common complication; but papillitis, or a lesser degree of change even than this, is said by French authors to be extremely common.

The chief complication affecting the ear is meningitic deafness. This is a common and very serious complication, serious because when it occurs it is apt to be permanent. The auditory defect generally begins early in the course of the disease, and usually before the end of the first week. It is usually bilateral, which adds to the seriousness of the trouble in the event of its becoming permanent.

5. *Arthropathies*.—A certain degree of painful stiffness, and even swelling of the joints, is not at all uncommon as a transitory symptom in cerebro-spinal fever. Occasionally, however, one joint shows evidence of much more intense infection, becoming red, swollen and very painful with the slightest movement. It may suppurate, and secondary infection may occur.

6. *Other complications* are the broncho-pneumonia already referred to in little children; occasionally pneumonia in adults; and enteritis.

LUMBAR PUNCTURE.—In any suspected case of meningitis a lumbar puncture is as clearly indicated as is puncture of the chest in a suspected case of pleuritic effusion, or a blood-count in a suspected case of leukaemia.

THE CEREBRO-SPINAL FLUID IN MENINGOCOCCUS MENINGITIS.—1. *Pressure and the amount*.—The pressure is generally more than 200 mm. of cerebro-spinal fluid as measured by a manometer fitted to the lumbar puncture needle. The amount of fluid which flows away before the normal pressure

is re-established depends upon the pressure and the consistency of the fluid; it averages about 30 c.c.

2. *Naked-eye appearance*.—Various grades of turbidity are met with, from very slight opalescence to a highly purulent exudate. The degree of turbidity varies with the stage of the disease at which the lumbar puncture is undertaken. In the invasion stage the fluid may be almost clear; in the acute meningitic stage the fluid shows marked turbidity; later, again, as the inflammatory phase passes, the fluid becomes clearer. The presence of blood probably always means that a vessel has been punctured by the needle. Some degree of clotting takes place when the fluid is allowed to stand, flakes of fibrin appearing at the bottom of the tube.

3. *Chemistry*.—The protein is increased in amount: instead of the faint opalescence which appears on boiling the normal fluid, a definite coagulum is produced, and an opaque ring appears when the fluid is poured gently on to the surface of strong cold nitric acid. A quantitative estimation of the protein shows that it may be present to the extent of 0.2 to 0.3 per cent. The globulin moiety of the protein is also increased. Sugar is greatly diminished and often absent. The chloride content also is lowered as in other forms of meningitis: it is seldom less than 700 mg. per cent., whereas in tuberculous meningitis a reading below 680 is the rule.

4. *Cytology*.—In the early or invasion stage of the disease there is a quantitative increase in the lymphocytic content, a fact which often escapes observation if the lumbar puncture be delayed. With the arrival of the acute meningitic inflammation the chief cell present is the polymorphonuclear, usually in large numbers. At the stage, therefore, at which most lumbar punctures are undertaken, the cell content is chiefly polymorphous (70 per cent. to 80 per cent.). Later, when the stage of chronic hydrocephalus ensues, the lymphocyte again becomes the dominant cell, and in much greater numbers than in healthy fluid. Most observers, however, describe cases of undoubted meningococcus meningitis in which the cell content is chiefly lymphocytic throughout. In the post-basic type of the disease the cells are most often lymphocytes for the greater part, and the same may be said of cases which are in a chronic stage whilst under investigation, whether the chief seat of the effusion be at the root of the bulb or elsewhere.

5. *Bacteriology*.—Films made direct from the cerebro-spinal fluid, or, better still, from the centrifuged deposit, show intra- and extracellular meningococci in the great majority of cases at some time or other in their course. If a careful search be made and no cocci are discovered, it must not be assumed that none are present until the device of incubating the fluid as a whole before it has been allowed to cool is undertaken, and until cultures made upon suitable media are found to be sterile. The number of cocci seen, and their disposition with regard to the cells of the exudate, are matters of great variability. These things depend in the main upon (a) the stage of the disease, (b) the intensity of the infection and (c) the influence of treatment.

Diagnosis.—The chief difficulty lies in not suspecting the presence of the disease. It is, of course, much more easy to bear in mind the possibility of cerebro-spinal fever during the presence of an epidemic than at other times. Cases which go undiagnosed, at least during the first part of their course, are those sporadic cases which generally happen to be typical.

The reason why it may not be possible to decide on clinical grounds whether meningitis is present or not is because several infective processes, other than that due to the meningococcus, are apt to produce symptoms highly suggestive of meningeal irritation. This state of meningeal irritation, when due to toxæmia and not due to actual meningitis, has been termed *meningism* or *meningismus*. The question whether such a state is entirely toxic, or whether it is due to definite though slight changes in the meningeal tissues which just stop short of an inflammatory exudate, is problematical.

The diagnosis of cerebro-spinal fever may be conveniently considered under three heads—(1) from various acute infective processes with toxæmia, leading to “cerebral” symptoms; (2) from certain acute cerebral diseases of primary origin; (3) from other forms of meningitis.

1. THE DIAGNOSIS OF MENINGITIS FROM TOXÆMIA MERELY.—The question is settled partly by the clinical data and partly by an examination of the cerebro-spinal fluid. In a case of fever with “head symptoms,” the following differential points should be borne in mind:

(1) *If headache and delirium synchronise, meningitis is probably present, and not merely toxæmia.*—Contrast an ordinary case of typhoid fever (toxæmia), in which headache and delirium alternate, the patient being free from pain when he is delirious, with cerebro-spinal fever (meningitis), in which the patient’s headache and delirium are both present at the same moment.

(2) *Vomiting.*—If this occurs not merely at the onset of the fever, but on subsequent days also, at a time when the invasion period of the infection may be said to be passed, it is evidence of meningitis.

(3) *Pulse and respirations.*—Irregularities in rhythm are in favour of meningitis, and so is a relatively low pulse-rate in comparison with the height of the temperature, provided typhoid fever can be eliminated.

(4) *Papillædema*, though its presence is much in favour of meningitis as against toxæmia merely, is not of much value in this connection, because it is usually absent at the early stage of the disease when the diagnostic problem requires urgent solution.

(5) *Cervical rigidity and tautness of the hamstrings*, though suggestive of meningitis, are often present in meningism.

These five points are worthy of the most critical investigation. All other clinical features that may be present are equivocal—they may be produced by a toxic state of the brain or meninges. This statement refers to the state of the pupils, whether contracted or dilated; the presence of *tâches cérébrales*; the absence of the superficial or of the deep reflexes; the “peevish” state of the patient with a resistant attitude; marked insomnia or persistent stupor.

(a) *Influenza.*—This probably gives most difficulty in actual practice. It should be noted that cerebro-spinal fever is very often mistaken for influenza, whereas influenza is rarely mistaken for cerebro-spinal fever. The reason for this lies in the fact that the diagnosis of influenza is too often by exclusion. Fever prolonged past the seventh day, in the absence of an inflammatory focus (bronchitis, pneumonia, pleurisy, sinusitis, etc.), is unlikely to be due to influenza, and should therefore lead to a critical revision of the diagnosis. A leucocyte count is often helpful.

(b) *Typhoid fever.*—The onset of the illness is nearly always a gradual

one, and the evolution of the toxic symptoms is much more deliberate than in cerebro-spinal fever. This is perhaps the most significant differential point clinically. The leucocyte count is very helpful, and may prove of great diagnostic assistance before Widal's test is available: the count is low in typhoid (2000 to 7000), but it is high in cerebro-spinal fever (15,000 to 40,000). The rose spots of typhoid do not appear until the eighth or tenth day, whereas the rash of cerebro-spinal fever which might be confused with these usually appears much earlier. If the spleen is palpable in cerebro-spinal fever this is the case early, whilst the disease is at its "septicæmic" stage; in typhoid the spleen can rarely be felt before the end of the first week. The dissociation of headache and delirium in toxæmia already referred to is strikingly seen in typhoid fever. Moreover, the disappearance of the headache altogether, which occurs so frequently in typhoid fever after the tenth day, is another point of distinction; although its severity may diminish, it is rarely absent so early in the course of cerebro-spinal fever. As soon as a positive Widal test is obtained (usually about the seventh to tenth day), this finding, together with a leucopenia, may be relied upon as decisive in favour of typhoid. A positive blood culture may often be obtained before the agglutination test is available.

(c) *Pneumonia*.—Acute pneumococcus infection is the most common cause of a toxæmic state leading to meningism; the patient is usually a child, but not always; the lung consolidation is often apical and therefore the more easily overlooked. The symptoms of meningeal irritation may precede the signs of pulmonary disease, in which case the diagnosis can only be settled by lumbar puncture, or they may concur with such signs, in which case some care must be exercised lest the case be one of cerebro-spinal fever ushered in by pneumonia. Here the leucocyte count is of no help, for there is a high leucocytosis in pneumonia as in cerebro-spinal fever. A blood culture may reveal pneumococci, or a lung puncture may yield direct evidence of the nature of the infection; but if the diagnosis is considered in serious doubt, it will probably be deemed wise to perform lumbar puncture.

(d) *Measles*.—The differential diagnosis between this disease and cerebro-spinal meningitis does not appear to be a matter of practical difficulty. But in the writer's experience, although no reference is made to the fact by authors, it is sometimes necessary to decide whether or not a mixed infection is present. There is good evidence that acute encephalitis may occur as an immediate sequel to measles.

(e) *Malignant small-pox*, on the authority of Milligan, simulates cerebro-spinal fever very closely, on account of the sudden onset, headache, vomiting and pain in the back. But as the eruption occurs on the third or fourth day the diagnosis is not left long in doubt.

(f) *Rheumatic fever*.—If cerebro-spinal fever begins with arthritis and profuse acid sweats, if the patient is an adolescent, and if the pains are specially referred to the joints, the diagnosis of rheumatic fever is at first pardonable. The addition of an erythema makes the simulation all the closer. The failure of salicylates to relieve the pain, or to reduce the fever, should at once arouse suspicion. The important distinction between early rigidity of the neck in meningitis and rheumatic stiffness—that the former tends to increase with examination, and the latter tends to decrease—should be remembered in this connection.

2. DIFFERENTIAL DIAGNOSIS OF CEREBRO-SPINAL FEVER FROM CERTAIN DISEASES OF THE CENTRAL NERVOUS SYSTEM.—The most important of these diseases sometimes introducing a difficulty is :

Poliomyelitis (infantile paralysis).—This disease, like cerebro-spinal fever, exists in epidemic and in sporadic forms. Of recent years there have been several small epidemics in England. Sporadic cases are very common. If the type of the disease is the usual one, little or no difficulty is introduced in diagnosis from cerebro-spinal fever, because the invasion or febrile stage is short and the degree of illness it involves is not great ; it is quickly followed by the paralytic stage, and the real nature of the malady becomes manifest. In the cerebral type of poliomyelitis, however—acute polioencephalitis—there may be considerable resemblance to cerebro-spinal fever, in that the patient often lies in a state of semi-stupor, and vomiting may occur and may persist for 2 or 3 days. It is, however, in the meningitic form of the disease that a real difficulty presents itself. There may be added to the headache and vomiting, pain and stiffness in the neck and spine, and even some degree of opisthotonos. Careful study of the cerebro-spinal fluid usually serves to differentiate the two diseases.

Encephalitis lethargica is differentiated by the characteristic lethargy (as against coma), the absence of rigidity and the spinal puncture findings.

3. DIFFERENTIAL DIAGNOSIS OF MENINGOCOCCUS FROM OTHER FORMS OF MENINGITIS.—(1) *Pneumococcus meningitis* is rarely primary ; almost always it complicates consolidation of the lung, or pleurisy, or otitis media, or infection of the nasal sinuses. When it occurs it is apt to be extremely acute.

(2) *Streptococcus meningitis* usually complicates some infective process about the skull, and most often this is middle-ear disease or sinusitis. In the majority of cases some surgical procedure has been attempted for the relief of the primary condition.

(3) "*Influenzal*" *meningitis* is a term applied somewhat loosely. Knowledge imparted by lumbar puncture makes the diagnosis of influenzal meningitis impossible from clinical grounds alone. Those cases in which Pfeiffer's bacillus is isolated from the lumbar puncture fluid, with the exudate of an acute meningitis, and definite symptoms, are not usually cases in which influenza has been suspected, still less diagnosed. Such cases are preferably termed "*Pfeiffer bacillus meningitis*."

(4) *Typhoid meningitis*.—A true infection of the meninges may occur in typhoid fever, but it must not be inferred that a patient necessarily has typhoid meningitis because the bacillus is grown from the lumbar puncture fluid. This may occur without clinical evidence of meningitis and without histological and chemical changes in the cerebro-spinal fluid characteristic of meningeal inflammation.

(5) *Tuberculous meningitis*.—This is by far the commonest form of acute meningitis and therefore deserves fuller mention. The most helpful points in a differential diagnosis from meningococcus meningitis are the following. Tuberculous meningitis is rarely so sudden in its onset, the meningitis symptoms being preceded by a longer period of malaise, which begins less abruptly than the invasion symptoms of cerebro-spinal fever. The temperature is seldom high, except as an ante-mortem event, the usual range being 99° to 101°. Retraction of the head is transient and ill-marked,

or is absent. Photophobia is more common than it is in cerebro-spinal fever. In adults aphasia is often a common and an early symptom. True (paralytic) squint is common. The "peevish" condition in children is much more marked during the first week. In both children and adults the depth of the stupor after about the tenth day is much greater. The discovery of tubercles in the choroid is pathognomonic, but these lesions rarely appear before the third week of the disease, and are therefore not of much service for diagnosis. Some authors lay stress upon the presence of signs of tuberculous disease elsewhere in the body as assisting in the diagnosis, but this is, of course, not true. Except in the case of adults, and by no means always then, there are rarely any such signs. The leucocyte count affords no differential help as from cerebro-spinal fever, a leucocytosis of considerable size (15,000 to 30,000) being present in tuberculous meningitis. The abdominal reflexes are usually retained, whereas in meningococcal meningitis they are prone to be lost early.

However high a degree of probability that a patient is suffering from meningitis may result from a general examination, confirmation of this view rests entirely upon the results of lumbar puncture. For three reasons it should not be deferred: it establishes the diagnosis that meningitis is present; it decides the nature of the infection; it is a valuable aid to treatment in the event of a positive result.

Prognosis.—The mortality in cerebro-spinal fever is undoubtedly higher in the epidemic than in the sporadic cases, if the post-basic meningitis of infants, in which the mortality is very high, be excluded. There are, however, no good figures upon which to base an estimate of mortality in the sporadic cases. In epidemics the mortality prior to the introduction of serum treatment was about 70 to 80 per cent. After its introduction the mortality fell to half this figure. With sulphonamide treatment the figure has probably reached 10 per cent.

The influence of age is noteworthy. The disease is extraordinarily fatal in infants (patients under 2 years of age). This statement holds good both for the post-basic cases which are so often subacute or chronic in character, and for the acute cases. The mortality is lowest between the ages of 5 and 10 years.

A fulminating form of onset is invariably bad, and the mortality in these cases is very high, if indeed it is not 100 per cent. In the cases with less vicious invasion symptoms, one or more of the following symptoms betoken a grave issue: early loss of consciousness, wild delirium, persistent insomnia, extensive hæmorrhagic eruption, cyanosis. Later in the course of the disease the worst sign is the appearance of hydrocephalus.

The degree of fever, the intensity of the headache, the amount of rigidity, the presence of marked emaciation, frequency and irregularity of the pulse, rhythmical respirations, the presence of herpes—none of these things yields any information of value in predicting the issue of the disease. *In few other diseases, if in any, is it possible for the patient to be so ill and yet to recover completely, as in cerebro-spinal fever.*

The most important fact bearing upon prognosis is the stage in the disease at which treatment is begun.

Treatment.—1. **PROPHYLACTIC.**—The principles governing prophylaxis are those applicable to infectious diseases in general. Although it would

appear that the healthy carrier is more responsible for the spread of the disease than the patient himself, it is none the less important to isolate every case of the disease and to exercise all precautions against further contact with healthy persons. Whenever possible the patient should be transferred to a hospital, and preferably to an institution where the staff is accustomed to deal with infectious diseases.

All contacts who are found to be carriers should be placed under quarantine, and should be kept there until the naso-pharynx is free from meningococci. The carrier should live as far as possible in the open air. For lavage of the naso-pharynx, and for a gargle, a weak solution of izal may be used, or peroxide of hydrogen, or a 1:1000 solution of permanganate of potash, adding 1.5 per cent. of sodium sulphate to assist penetration (Gordon). For spraying the nose or fauces, a 1 per cent. solution of iodine with 2 per cent. of menthol in parolein may be used.

The use of a meningococcus vaccine for the purpose of clearing the throat has not proved to be successful.

2. CURATIVE.—(1) *Drug treatment*.—The introduction of sulphanilamide has revolutionised the treatment of this disease. It is of vital importance that the drug should be given at the earliest possible moment after the diagnosis has been made or is strongly suspected. (For details of sulphonamide and penicillin therapy, see pp. 11, 17, 18.)

The persistence of an ensuing temperature of 99°–100° does not necessarily imply that the infection is still active.

(2) *Serum treatment*.—The indications for the use of serum are (a) intense toxic symptoms, (b) unsatisfactory response to sulphonamides and (c) evidence of idiosyncrasy to these drugs (see p. 17). In (a) the serum is used as supplementary to sulphanilamide, not as a substitution for it. It is given intrathecally in doses of slightly less bulk than the amount of cerebro-spinal fluid removed. In highly toxic cases it may also be administered intravenously, in doses of 50–100 c.c. diluted to 250–500 c.c. with normal saline.

The serum may be allowed to flow by gravity into the *lumbar cisterna* following lumbar puncture, or it may be injected with a syringe which fits the lumbar puncture needle; the serum must be warmed to body heat and the injection made very slowly. The volume of serum injected must not exceed that of the cerebro-spinal fluid withdrawn. Serum may also be introduced into the *cisterna magna*. To reach this the needle must pass through the posterior atlanto-occipital ligament, which is not nearly so thick and resistant as are the interspinous ligaments between the spinous processes of the lumbar vertebræ, before entering through the foramen magnum. The posterior rim of the foramen magnum in the adult is just over 1 cm. from the posterior surface of the medulla oblongata, whereas a distance of only 0.5 cm. separates the lowest part of the medulla from the posterior arch of the atlas; the puncture therefore should be made as near to the upper border of the atlanto-occipital ligament as possible, and the needle inclined upwards. The patient lies on his left side, with the head erect; if head retraction be present, a general anæsthetic is essential in order that the requisite position may be assured. The uppermost bony point palpable in the mid-line of the back of the neck is the spine of the axis. The skin in this area is cleaned and, if general anæsthesia is not used, the tissues are infiltrated with sterile local anæsthetic.

After this has had time to act, the skin is nicked with a sharp-pointed knife just above the level of the spine of the axis in the middle line. A fine lumbar puncture needle with a very short bevel is now inserted through the nick, and its direction so adjusted that it is continuous with a line passing through the level of the external auditory meatus to emerge on the forehead about 3 cm. above the bony prominence at the root of the nose, known as the glabella. The needle pushed steadily along this line will impinge on the occipital bone just posterior to the foramen magnum; the correct depth is thus determined and the needle withdrawn, almost to the skin, its direction altered slightly downwards and on reinsertion the point enters the cisterna just below the rim of the foramen; this is apparent to the operator by the sense of diminution in resistance to the passage of the needle. The cisterna magna is entered at a distance of 4.5 cms. from the skin in an adult of average build.

(3) *General management.*—The diet is to be adjusted to the patient's condition. The disease is an exhausting one, and as full a dietary as is consistent with the state of the digestive secretions is to be allowed. If the fever is a conspicuous feature, and the patient is drowsy or delirious, the mouth is usually dry; the diet is then necessarily restricted to fluids, which should be given in the form of diluted milk, and freshly prepared meat essences, in small quantities at frequent intervals. Water should be given freely. If the patient is in a state of stupor the act of swallowing must not be relied upon; feeding must then be by the passage of a nasal tube three or four times in the 24 hours. According to the age of the patient, from 5 to 10 ounces of citrated milk and water (equal parts), or of peptonised milk, or of beef essence are allowed to run into the stomach from a funnel attached to the tube and held at the necessary height above the bed. If vomiting is troublesome, peptonised milk should only be used, or whey or albumin water. If this symptom is persistent, it may be advisable to put no food at all into the stomach for 24 to 48 hours, relying upon saline injections (5 to 20 ounces according to age) per rectum every 6 hours, supplementing these, if thought desirable, by the subcutaneous use of a 10 per cent. solution of dextrose in normal saline.

The bowels are usually constipated; it is therefore frequently necessary to use purgatives, avoiding salines if sulphonamide is being given. If the patient is comatose early in the disease, when treatment is beginning, it may be advisable to give 2 minims of croton oil in butter or moist sugar.

Urinary difficulties do not usually occur unless the patient is unconscious, in which case it is important to bear in mind the possibility of retention, which may lead to "overflow incontinence." This condition indicates the use of the catheter, with the customary care in the matter of asepsis.

(4) *The treatment of certain symptoms.*—Headache is usually the most distressing symptom calling for special treatment. Phenazone, caffeine, and acetylsalicylic acid may all be tried in full doses; morphine may be imperative in some cases, because nothing else may be of any service. Restlessness, delirium and insomnia,—if these symptoms are troublesome a trial should be given to some such combination as the following: R Ammon. bromid., grs. 10-30; Tr. valerian. ammon., min. 10-30; Syr. chloralis, min. 20-120; Aquam ad fl oz. 1 S.—Secundis horis ad doses iv-vi.

The pains and the stiffness are best treated by warm baths at a temperature of 102° to 104° F.

If the delirium is exhausting or the condition verges upon mania, vapour of chloroform may be used, or morphine with atropine may be given. Hyoscine should be avoided.

In arthritis the affected joint is best treated by fixation, by the application of hot stupes, and by liquid. If the effusion becomes considerable, or does not quickly yield to these measures, the joint should be aspirated.

(5) *The repetition of the lumbar puncture.*—A lumbar puncture of necessity precedes the diagnosis. When sero-therapy is in force the puncture is, of necessity, repeated at each dose of serum. There remains the question of the therapeutic value of thecal drainage here as in the other forms of pyogenic meningitis undergoing sulphonamide treatment. There are reasons for thinking that drainage at certain intervals, especially in children, tends to prevent the development of the most serious of the complications of the disease, a state of hydrocephalus. The writers are of opinion that the process has beneficial effects upon the course of the disease in many cases. This, notwithstanding the fact that whole groups of cases have been successfully treated by chemotherapy with no further lumbar puncture than that made for diagnosis.

(6) *Treatment of hydrocephalus.*—If a condition of hydrocephalus has been diagnosed, it is advisable to tap the lateral ventricles and to inject serum. This procedure is not so difficult nor so dangerous as may be supposed.

(a) The patient is usually an infant with open fontanelles. The region of the anterior fontanelle is shaved and the skin is sterilised. A stout needle, to which a syringe can be attached, is inserted at the lateral angle of the fontanelle, and is gently pushed towards the mesial line for a distance of an inch or an inch and a half. In older patients a special drill may be necessary. The fluid is usually under considerable pressure, so that it becomes quickly known when the needle reaches it. It is not necessary or advisable to attempt to withdraw more fluid than comes into the syringe with very gentle aspiration. With great care, an amount of serum less in bulk than the fluid withdrawn is now introduced into the ventricle.

(b) In older children and adults the operation of decompression becomes necessary; and here again, though a much more serious procedure, the practitioner should not hesitate to give the patient the benefit of the operation and of the use of serum by this special route.

HORDER.

A. E. Gow.

TETANUS

Synonym.—Lockjaw.

Definitions.—An infective disease, due to the toxins of the clostridium tetani, and showing itself by tonic spasm of the masseter and other muscles with paroxysmal exacerbations.

Ætiology.—The bacillus of tetanus is a slender rod 4 to 5 μ in length and from 0.3 to 0.8 μ broad. It is a spore-bearing anaerobe. The vegetative

forms are slightly motile, and when stained by special methods show numerous fine flagella arranged all round the bacillus. In material from infected wounds, and usually in cultures after 24 hours' incubation at 37.5° C., spores occur. These are terminal, giving rise to the characteristic drum-stick appearance. As cultures grow older the numerical proportion of spore-bearing forms increases, and in very old cultures only spore-bearing forms or spores are found.

Distribution.—In nature the tetanus bacillus is found in the soil of highly-manured districts, and in the dejecta of various animals, especially the herbivora, in the intestines of which it exists without causing pathogenic effects. By comparison with the widespread distribution of the bacillus and its spores the disease is rare. In infected wounds the bacillus occurs with other spore-bearing anaerobes associated with pyogenic cocci, and saprophytic organisms of various kinds. In consequence of its association, in nature and infected wounds, with other organisms, the bacillus is difficult of isolation, as a large proportion of the associated organisms grow with much greater rapidity. Use is made of the fact that the spores will resist a temperature of 80° C. for an hour. Suspected material is inoculated into agar or serum-agar slopes or deep tubes of glucose-agar, and incubated for 48 hours. The culture is then subjected to a temperature of 80° C. for three-quarters of an hour, and subcultures are made on agar plates which are incubated anaerobically. By this means all non-sporing bacteria, and the vegetative forms of the spore-bearers, are killed, and only spore-bearing organisms remain to be dealt with.

The disease follows *injury* to the tissues in most cases, and even when no injury is known to have occurred, it is highly probable that some slight abrasion has been present. The term "idiopathic tetanus" has been given to those cases in which no discoverable injury is present. Those wounds, usually of the hands, in which the tissues have been badly damaged rather than cleanly cut, are specially liable to be followed by tetanus infection. Cases have occurred from the use of contaminated gelatin used in subcutaneous injections, grey wool employed as padding for splints, and from catgut sutures similarly infected.

Tetanus is more common in tropical than in temperate zones. A special form of the disease, *tetanus neonatorum*, is peculiar to the tropics, and results from sepsis in attending to the child's navel. This variety, which has occurred in epidemics, is "almost peculiar to infants of the filthy poor" (Hirsch, 1886).

Pathology.—In nature the disease is produced by the introduction of infected material through an abrasion or wound, which may be so minute as to escape detection. Probably there is no such thing as idiopathic tetanus, but infection is possible through the bronchial or even intestinal mucosa.

If the bacilli or spores, free from toxin or from pyogenic cocci, be introduced into an animal, infection may fail to occur, the protection afforded being probably accounted for by phagocytosis, for if spores enclosed in a paper sac be introduced into a susceptible animal infection occurs, as the sac protects the spores from phagocytosis. The presence of pyogenic cocci, other micro-organisms, and the fragments of bone and foreign material incidental to compound fractures and gun-shot wounds, all conduce to the conditions favourable to growth of the tetanus bacillus.

The *period of incubation*, following infection with tetanus bacilli, varies with different animals. In man a period of from 2 to 14 days occurs, but the period may be longer, and as a rule a long incubation period means a more favourable prognosis.

Tetanus toxin.—The tetanus bacillus, like the diphtheria bacillus, produces its pathogenic effects by reason of the soluble toxin it elaborates. Bacterium-free filtrates of cultures, as shown by Kitasato, when injected subcutaneously or intravenously into mice, cause tetanic spasms, at first in the neighbouring muscles and later more generally, and death has resulted.

Tetanus toxin is one of the most powerful poisons known, the fatal dose of a probably impure toxalbumin for a mouse being found by Brieger to be 0.0005 mgm.

Different degrees of resistance to the toxin are shown by different animals. The horse and man are the most susceptible. On a basis of weight the horse is twelve times and the guinea-pig six times as susceptible as the mouse, while the hen is two hundred thousand times as resistant. The incubation period is shorter when toxin is intravenously injected than when introduced subcutaneously, and is shorter in smaller than in larger animals.

It has been proved that toxin is absorbed by the end-plates of motor nerves. This was shown by severing the sciatic nerve of an animal near the spinal cord. The corresponding hind limb was then injected with toxin. A portion of the divided nerve was then placed in another animal and tetanus resulted, while if the nerve were cut distally, and a proximal portion thereof were transplanted, no infection occurred, though in both cases the nerves were equally bathed in lymph containing toxin. And, again, if an excess of toxin be injected into a sound limb only that portion of a nerve distal to a section in another limb shows absorption of toxin. Introduction of a lethal dose of toxin into a nerve such as the infra-orbital, containing no motor filaments, is not followed by characteristic tetanus symptoms.

The toxin passes centripetally up the nerve and affects the motor nerve cells corresponding thereto, thus accounting for the longer incubation period in larger animals. If antitoxin be injected into a mixed nerve, such as the sciatic, toxin is prevented from passing up that nerve; but toxin injected into a similar nerve will act lethally even though a large excess of antitoxin had been previously injected intravenously. In one case, indeed, it was shown that a dose of toxin injected into the sciatic nerve of a highly immunised animal caused tetanus. Possibly these results are accounted for by the now well-known difficulty of bringing antibacterial and antitoxic bodies in the blood to bear on the cells of the central nervous system, a difficulty which has been met, to a certain extent, by the introduction of intrathecal medication.

Symptoms.—The incubation period has already been referred to. The earliest symptom is, in the great majority of cases, the so-called *trismus* or painless tonic spasm of the masseter muscles. Beginning as a slight stiffness, this increases until the jaws are firmly clenched, the patient being unable to open the mouth. The stiffness may involve the muscles of the neck at the same time as the jaws, or a little later. The facial muscles are affected next, and the facies presents the *risus sardonicus* due to the tension in the frontalis and in the muscles at the angles of the mouth. The muscles of deglutition

are another group early affected. There is, from these parts, a steady spread of the spasm to the trunk and then to the limbs. Rigidity tends to appear early in the rectus abdominis and in the adductors of the thighs. The tendon jerks are exaggerated and attempts to elicit them produce spasms, local or general; attempts to elicit the plantar reflex may cause extension of the knee (Gordon Holmes). The tonic spasm in the muscles of the trunk, which may develop in from 12 hours to a week after the appearance of trismus, usually show exacerbation in paroxysms, with resulting postures termed respectively opisthotonos, emprosthotonos and pleurothotonos, according as the muscles of the back, abdomen or one side of the body are in a state of spasm. These paroxysms may be induced by divers irritants, and are agonisingly painful; the earlier they occur the more grave is the prognosis. Retention of urine is common.

Less common manifestations include a local contracture of muscles in the neighbourhood of the wound, which may precede trismus or more general spasm by several days; the localisation of stiffness and spasm in tetanus may be a result of immunisation. Thus, in a wound of the forehead there may be a facial palsy or an ophthalmoplegia on the same side or, with a wound of the hand or foot, painful spasm of the muscles of the limb may develop before spasm appears elsewhere. In some of these local forms general spasms may be absent throughout or, if trismus is present, this may be transient. In "*local tetanus*" the incubation period is sometimes as long as 30 days.

The disease is often apyrexial, but in some cases the temperature rises with the development of the general symptoms, which include headache, pains in the back, anorexia, constipation, insomnia, yawning, sweating and a facies of great anxiety. Hyperpyrexia may precede death. Consciousness remains clear. The cerebrospinal fluid is unaffected.

Course.—The course of the disease is variable. Sometimes it is as short as 4 or 5 days, the patient dying of spasm of the glottis, asphyxiation, bronchopneumonia, heart failure or exhaustion. Other cases, less fulminant, last from 7 to 14 days. A few seem to deserve the term "*chronic*."

Diagnosis.—A relatively trivial disease which may, however, cause some anxiety from its resemblance to the trismus of tetanus, is the fixation of the jaw seen in certain cases of *septic throat* and *septic*, especially impacted, *teeth*, with phlegmonous involvement of the floor of the mouth, periosteum, etc. Careful examination of the mouth nearly always suffices to determine the real nature of these cases, and the presence of enlarged and tender cervical glands assists the diagnosis.

Strychnine poisoning presents features resembling tetanus in that the spasms are very similar in both diseases. But between the spasms in strychnine poisoning the muscles are relaxed, a condition never seen in tetanus. Another point of distinction is the fact that trismus and cervical rigidity never exist alone in strychnine poisoning, whereas they frequently do in tetanus.

In any doubtful case of injury, in which there are damaged tissues, bacteriological investigation of the exudate and of material from the depths of the wound should at once be made.

Prognosis.—This is always grave. The mortality in a large series of cases appears to be nearly 60 per cent. (Hill). Infants and children rarely recover. The absence of fever, a more or less normal pulse-rate, a long

incubation period, and a slow development of the symptoms are favourable points. If the patient reaches the tenth day of the disease, his chance of recovery is considerably increased.

Treatment.—1. **PROPHYLACTIC.**—All wounds of a suspicious character should be well curetted under a general anæsthetic, the raw surface should be thoroughly treated with antiseptic and antitoxin administered.

Antitoxin has for some time been used in connection with wounds infected with road-sweepings, or garden soil, and in America chiefly in cases of wounds connected with Independence Day celebrations, in consequence of which injections a very definite fall in the death-rate resulted.

During the War of 1914–1918 antitoxin was used on an extensive scale. During the early period, with no special arrangements for prophylaxis, the incidence was about 8 per 1000. Later, with the use of 500, and then 3000 international units (I.U.), of antitoxin, the incidence fell to 1 in 1000. Following passive immunisation induced by prophylactic antitoxin, cases which do develop tetanus tend to have a longer incubation period and the disease may remain “local.” But such passive immunity does not persist for more than 3 weeks; hence to ensure protection the dose of antitoxin must be repeated at fortnightly intervals where wounds do not heal.

In 1924 Ramon and Zoeller showed that tetanus toxin might be so treated as to lose its toxicity and still retain its antigenic power. The material, called “toxoid,” has been proved of great service as a preventive agent. At the R.A.M. College it has been proved that two doses of 1 c.c. each of toxoid, given at intervals of 6 weeks, confer immunity lasting at least 2 years. This is now the practice in the British Army before a man goes on active service. The second injection is most essential in the production of active immunity for, following it, the rise in antitoxin content of the patient's serum is far greater than that consequent upon the first.

2. **CURATIVE.**—Keep the patient as quiet as possible in a dark and noiseless room. Feeding may be impossible by mouth, in which event nasal feeding may be attempted, and if this, too, is impossible because of spasm, recourse must be had to glucose-saline rectal drip.

It is profoundly important that no delay whatever should occur in the use of antitoxin. Injection may be made intravenously, intramuscularly, or intrathecally. The last route achieves easier access to the affected nerve cells, though it is usually, and rightly, combined with other methods; the great disadvantage lies in the liability of the manipulation to induce or accentuate muscular spasms.

Provided there be no contra-indication to the administration of horse serum—freedom from previous serum therapy, freedom from allergic manifestations which might necessitate rapid desensitisation (see p. 7), antitoxin may be injected undiluted into the vein and theca. As soon as symptoms appear, 200,000 units are given intravenously and 80,000 intrathecally. If the wound involves a limb, a further 10,000 units should be injected into the tissues on the proximal side. Antitoxin is excreted slowly and its presence in the circulation has been demonstrated at least 10 days after a large single dose given by the intravenous route (Cole). If all goes well, therefore, there is probably nothing to be gained by repeating the dose under 7 days; in extensive wounds 50,000 units should be given at weekly intervals by the intravenous route until spasms cease. A similar dose should be administered

at least an hour before any further surgical treatment or manipulation is undertaken.

Before the onset of tetanic convulsions, a mixture of chloral grs. 15 and bromide grs. 20 given by mouth two- or four-hourly, or luminal grs. 1 by mouth or subcutaneously as often as required, is indicated to lessen excitability and procure sleep. Avertin or paraldehyde administered per rectum are the best remedies by which to control severe spasms. For a man weighing 10 stones (63 kgm.), 6 c.cm. of avertin or 20 c.cm. (5 dr.) of paraldehyde shaken up in 200 c.c. of normal saline, should suffice to hold them in check for 4 to 6 hours, after which the dose may require to be repeated. While the patient is under the influence of avertin trismus may be relaxed and attempts at feeding are most likely to be successful 2 or 3 hours after its administration. Chloroform vapour is also of value, but when spasms are severe it cannot be inhaled. A more or less continuous use of morphine or hyoscine is an alternative measure.

Less success has attended the therapeutic use of tetanus antitoxin than is the case with diphtheria antitoxin. This result is largely, if not entirely, accounted for by the relative slowness in the onset of symptoms in tetanus as opposed to diphtheria. The argument for the prophylactic use of antitoxin in every case of a wound contaminated with road material or soil contaminated with animal excreta becomes correspondingly strengthened.

ANTHRAX

Synonyms.—Wool-sorter's Disease; Splenic Fever of Animals.

Definition.—An acute infective disease caused by the *Bacillus anthracis*. There are three clinical forms of the disease, according as the lesion is in the skin (malignant pustule), in the lung (pulmonary anthrax), or in the intestine.

Ætiology.—*B. anthracis* is a large Gram-positive bacillus possessing a capsule. On artificial media it grows in long filaments which, owing to the fact that the filaments do not readily break up into individual bacilli, tend to bend upon themselves and thus cause the outlines of the colony to assume a whorled appearance that is characteristic. Spores always develop in cultures in the presence of free oxygen.

In the tissues, however, the bacilli occur in straight rods measuring from 5 to 10 μ by 1 to 1.5 μ , the longer forms generally being found in attenuated cultures, and the bacilli found in the gelatinous œdema are usually longer than those found in blood. Spores never develop within the infected animal since free oxygen is necessary. The micro-organism is non-motile.

In the herbivora, especially sheep and cattle, the disease occurs epidemically and the infection assumes a septicæmic type. The spleen may be two or three times its normal size, and on section may be diffuent. An impression preparation from the cut surface shows enormous numbers of bacilli together with blood cells and mononuclear leucocytes. The liver and kidneys are in similar condition, and the lymphatic system is extensively involved.

The bacilli in the blood are invariably in the vegetative form, and it is only after being voided from the body that they produce spores, these being extremely resistant to adverse influences. It is claimed that spores may

remain on the ground in a state of latent activity for as long as 12 years. But it is suggested by M. Fadyear and others that soil infection counts for little in this country, most cases being traceable to imported food stuffs, hides and brushes.

The carnivora are relatively immune, especially the dog.

Man occupies an intermediate position, and the disease is always communicated to him directly or indirectly from animals. Two principal forms occur, malignant pustule, a local infection through a cut or abrasion of the skin or a hair follicle, and wool-sorter's disease, an infection starting in the trachea and bronchi from the inhalation of dust containing spores.

Infections of the intestinal tract may occur but are rare. Such infections must originate from spores, as the bacilli do not withstand the action of gastric juice.

Bacteriological Diagnosis.—In a case of suspected malignant pustule direct microscopic examination will usually show the bacilli in the fluid in the surrounding vesicles. Sometimes examination of the sections of the excised malignant pustule is necessary. Cultures on agar will show in 24 hours the characteristic wavy-outlined colonies. Blood cultures in man never show the bacilli until just before death. Putrefaction rapidly destroys anthrax bacilli, hence the recognition of the bacillus in putrefying tissues entails careful bacteriological examination and animal experiments.

A guinea-pig may be inoculated with suspected material, and if anthrax be present will usually die within 2 days, and the bacilli may be demonstrated in the spleen.

Immunity.—Pasteur, noting that one attack of anthrax immunised an animal, elaborated a method of artificial immunity. He attenuated cultures by growth at 42.5° C. Sheep survived when inoculated with such cultures, and proved immune to a subsequent injection of a highly virulent living culture. By carrying out this process of active immunity the mortality among animals was greatly lessened. Marchoux showed that the serum of such animals conferred a certain degree of passive immunity; and Sclavo, by using a mixture of such immune serum and progressively attenuated cultures and virulent cultures, obtained very high degrees of immunity in the ass. Sclavo's serum is stable, and if given in quantities of 40 to 100 c.c. at an early enough stage in the disease is almost always successful.

Formerly the local effects of infection were considered due to the mechanical damage to the tissues by the rapid multiplication of the bacilli. Later it was considered that the tissues were injured by simple deprivation of oxygen. Now the result is considered to be a toxic phenomenon. There are three clinical forms of the disease.

I. MALIGNANT PUSTULE.—The site of infection is nearly always upon an exposed part of the body—face or hands or forearms. The incubation period appears to be very short, perhaps not longer than a few hours. A small red papule forms, which rapidly becomes vesicular and then incompletely pustular. By the time vesication occurs there is a surrounding zone of intensely red cedema, becoming a brawny induration by the end of the second day. By this time a ring of secondary vesicles often surrounds the initial lesion, which has now formed a dry and almost black scab, generally raised above the surface of the affected skin. A frequent associated lesion in the case of the arm is lymphangitis, spreading upwards

to the lymph glands, which become enlarged and painful. There is rarely much pain at the site of the initial lesion, though there is usually a good deal of itching and tenderness. Fever is almost constant, and in severe cases may be quite high. The patient is then very ill, with intense toxic symptoms. Mild cases occur, however, and in them both the local and the general symptoms are much less marked.

The prognosis turns upon the severity of the symptoms, especially of the toxæmic state. Death is sometimes very rapid—it may occur within the first week.

In some cases the initial papule and vesicle are ill-marked, but the attendant œdema is excessive (*malignant œdema*). The mortality in this type of the disease is a good deal higher than in the type in which the pustule is well formed.

II. PULMONARY ANTHRAX.—In this variety of the infection the bacilli are inhaled with dust from infected hair or wool. The result is the rapid development of fever, generally ushered in by a rigor, with very intense toxic symptoms and the signs of bronchitis. Cerebral symptoms develop, with great weakness. The whole course of the disease may be very short, even as brief as 24 hours. Recovery probably never takes place, even if the diagnosis has been made at an early stage.

III. INTESTINAL ANTHRAX.—This is probably the least common form of the disease. The infection is due to eating meat or drinking milk from animals suffering from splenic fever. The symptoms are those of a severe gastro-enteritis—fever, vomiting, diarrhœa and intense weakness. The spleen is enlarged. This form of the disease has been found to occur in small epidemics. The mortality is high, though not so high as in II.

Treatment.—(i.) PROPHYLACTIC.—This consists in the specific immunisation of animals subject to the disease, the complete destruction of dead bodies, and in the careful disinfection of all skins, hair and wool, before these are handled in any industrial occupation.

(ii.) CURATIVE.—General measures (rest, etc.) are taken towards the prevention of a general infection. The pustule is kept clean, but is neither cauterised nor incised. A large dose of Sclavo's anthrax anti-serum (40 c.c. at least) is given as soon as possible by the intravenous route. This is repeated intramuscularly at intervals of 12 to 24 hours, the dose being gradually reduced. If the serum is not available, 0.6 to 0.9 g. of neoarsphenamine or one of its equivalents may be injected intravenously and repeated in 48 hours. Some observers consider this treatment to be as good as by serum for malignant pustule, provided it be given within 4 days of the onset of the disease. Treatment by sulphapyridine, given intensively (see pp. 17-18), has proved successful. So also has penicillin.

GLANDERS

Definition.—An infectious disease, occurring not infrequently in the horse and in the ass, occasionally transmitted to man, and characterised by the formation of granulomatous nodules in the nose (glanders), and in the subcutaneous tissues (farcy).

Ætiology.—The *bacillus of glanders*, or *Bacillus mallei*, is a short rod,

straight or slightly bent, of 3 to 4 μ in length by 0.5 to 0.75 μ in thickness. It is non-motile, and possesses no flagella, nor does it form spores. It can be cultivated on ordinary media at 37° C., but gives a more characteristic growth on potato.

The bacillus stains somewhat faintly with the usual aniline dyes, so that a mordant, such as carbohc acid, is usually employed, but even when deeply stained there is a tendency to decolorise rapidly. The staining is markedly irregular, this irregularity being a diagnostically helpful point. It is Gram-negative.

Pathology.—The disease chiefly affects horses, mules and asses—the latter being the most susceptible. Horned cattle are immune, but goats and sheep are occasionally infected.

In the horse, infection may take place through any abrasion of the skin, but most frequently through abrasion of the nasal mucous membrane from infected water-troughs or feeding-mangers. The infection may be acute or chronic. In the acute form (glanders proper) there is fever and prostration, and in two or three days there occurs ulceration of the nasal mucosa with a sero-purulent discharge, leading on to involvement of the lungs, and death within a few weeks. In the chronic form—farcy—there is involvement of the lymphatic system associated with the original site of entry. The lymph vessels become enlarged—farcy pipes—and irregular thickenings—farcy buds—occur, which may soften and suppurate.

The disease may be latent, and can then only be diagnosed by the “mallein” test. In the human being the infection is generally derived directly from the horse, and is therefore usually confined to those in close connection with horses; but the disease has been contracted in the laboratory.

The toxin of *B. mallei* or mallein is an endotoxin, being derived from the bacterial bodies, in which respect it differs markedly from the toxins of tetanus and diphtheria bacilli. One of its chief characteristics is its resistance, it being capable of withstanding temperatures of 120° C. and prolonged storage with but little loss of strength. It is prepared by growing cultures in glycerin broth for 3 or 4 weeks, and sterilising these by boiling or autoclaving at 115° C. The cultures are then allowed to stand, and the supernatant fluid being decanted off, this is then filtered through a Chamberland filter. The resultant filtrate, to which one-half of 1 per cent. of carbohc acid is added, constitutes mallein. It contains the soluble portions of the bacteria, and substances from the altered medium, and is a similar product to tuberculin. It is used in doses of 1 c.c. to detect a glanders infection in the horse. As the reaction in a “glandered” animal is severe, both locally and constitutionally, it is unsuitable for use in man.

FORMS OF THE DISEASE.—Both glanders and farcy have been known to occur in man in acute and in chronic forms. All forms are rare.

Symptoms.—1. **ACUTE GLANDERS.**—The incubation period varies, but is in most cases 4 days. At the site of infection in the nose there occurs an inflammatory swelling surrounded by cedema and lymphangitis, with a papular eruption soon becoming pustular. In a few days other and similar swellings appear, which soften and ulcerate, so that the mucosa of the nose becomes generally infected, leading to profuse muco-purulent discharge. The whole nose swells; it may be very considerably. The ulceration extends deeply so as to involve the cartilage and bone. The cervical

lymph glands are usually enlarged and may soften, forming abscesses. Constitutional symptoms are present by this time, and death, usually with pneumonia, occurs about the middle of the second week.

2. **CHRONIC GLANDERS.**—This form resembles closely the disease as seen in the horse. There is a chronic profuse coryza, associated with widely scattered muscular and subcutaneous nodules. Unless the nature of the disease is suspected, it may go undiagnosed for some time.

3. **ACUTE FARCY.**—This is the form of the disease resulting from accidental inoculation of the skin. A local lesion of a highly inflammatory kind leads quickly to a spreading zone of lymphangitis, subcutaneous nodules (farcy buds) appearing in the track of the infection, softening and forming abscesses. The patient becomes severely ill, with symptoms of a general infection, and the course of the disease is of much the same duration as in acute glanders.

4. **CHRONIC FARCY.**—This only differs from acute in that the "buds" are associated with much less inflammatory reaction, the constitutional symptoms are much less severe, and the course of the disease is much longer. A few of the cases have extended over 12 months.

Diagnosis.—Acute glanders has been mistaken for small-pox, owing to the likeness of the papulo-pustular eruption to the specific eruption of this disease. The chronic forms are at times mistaken for the other infective granulomata (syphilis, tuberculosis and actinomycosis). Exact diagnosis turns upon bacteriological methods, direct or indirect.

The *bacteriological diagnosis* in man may be simple if a superficial swelling exists which may be opened. Direct cultures may be made therefrom, preferably on potato, and a rapid diagnosis made. It may be, however, that weeks elapse before such an opportunity occurs, or before some deeply situated swelling calls for operative interference. In such cases serum reactions, such as the complement-fixation test and agglutination, are indicated, and in a case watched by one of the authors the diagnosis was made by the opsonic test several weeks before the bacilli were cultivated from the tissues.

If material containing *B. mallei* be injected intraperitoneally into a male guinea-pig, tumefaction and suppuration occur in two or three days in the tunica vaginalis, and the bacilli can be recovered therefrom after about six days.

Treatment.—**PROPHYLACTIC.**—The utmost care must be taken in nursing, destruction of old dressings, etc.

The site of inoculation, if obvious, should be excised, and the underlying tissues should be treated drastically by strong antiseptics. All abscesses should be opened promptly and efficiently drained. The general symptoms are met by treatment similar to that given in any septicæmia.

JOHN MATTHEWS.

TULARÆMIA

Synonym.—Deer-fly Fever; Pahvant Valley Fever; Ohara's Disease.

Definition.—A plague-like general infection of small rodents, hitherto

confined to the United States, Japan and a district in Siberia; also recently in Norway, communicable to man. The disease has the peculiarity, in which it resembles Malta fever, of being extremely infective to laboratory workers handling the causative organism, *Bacterium tularensis*, and attention to this aspect has been drawn by an important paper by Professor Sir John Ledingham and Dr. F. R. Fraser, in the *Quarterly Journal of Medicine*, vol. xvii., describing three cases occurring at the Lister Institute.

Ætiology.—In 1911 M'Coy, during plague work among ground squirrels in California, discovered a plague-like disease not due to *Bacillus pestis*, and in 1912 M'Coy and Chapin isolated the specific organism from the blood of infected animals, and it was named *Bacterium tularensis*. Subsequently the organism was found in various rodents, and endemic centres of the infection have been recognised in many areas of North America. The first human case of infection appears to have been reported by Pearce in 1910, but bacteriological proof connecting it with *B. tularensis* was provided by Francis subsequently. Where the infection is endemic among rodents, human cases are not uncommon, and possibly some have recovered unrecognised. The infection is conveyed from animal to animal by various blood-sucking parasites. The fæces of infected bugs have been shown to be infective. Polluted water has recently been thought to be a source of infection in Norway and U.S.A. There is thus no difficulty in understanding how endemic centres of infection are kept up, and human infections in the field are readily understood. But it is difficult to explain the cases of infection in laboratory workers. It is suggested that a possibility is respiratory infection during the anæsthetising of experimental animals, when coughing is not uncommon, and the bacillus is certainly contained in bronchial secretions, as well as the excreta generally. The question appears to be parallel to the difficulty of explaining the great liability to laboratory infections with *Br. melitensis*.

B. tularensis is a minute, Gram-negative cocco-bacillus, measuring, according to M'Coy and Chapin, 0.3, with a breadth of 0.2 μ . It is not easily stained by the ordinary dyes, unless a mordant, such as carbolic acid or aniline, is added. It is refractory to growth on ordinary media, the original cultures being obtained on a medium composed of egg-yolk. It will grow readily on serum glucose agar if a piece of rabbit spleen be added thereto.

Pathology.—In animals, nothing characteristic is found. At the site of inoculation some diffuse necrosis may be seen, and occasionally swelling of the corresponding lymph glands. The spleen, liver, lungs, and kidneys may show small necrosis areas. Human cases contracted in the field, probably from some blood-sucking fly, will show a local ulceration at the site of the bite, with swelling, and possibly suppuration, of the local lymph glands. Cases contracted in the laboratory provide no pathological data, for there is no evidence of the portal of infection, and the blood shows no characteristic changes.

Symptoms.—The infection expresses itself in two ways: (1) Dealers in rabbits may develop a necrotic papule, which is followed by acute lymphadenitis in the area affected. Suppuration may occur, with considerable pyrexia and toxæmia. (2) Laboratory workers studying the infecting agent have suddenly developed pyrexia, with marked malaise and no localising symptoms. The temperature subsided at the end of 3 weeks in the American series of cases, but it remained up for a longer period in the

London series, and in one case there were irregular rises of temperature for a period of a year. The marked features of the majority of the cases were the malaise, the recurrent nature of the fever, and the prolonged inability to work.

Diagnosis.—In endemic areas, people handling rabbits and other rodents, who develop fever, with or without localising signs of insect bites, should be under suspicion. In this country, only laboratory workers are likely to be infected. In either case, the diagnosis depends upon specific agglutination of *B. tularensis* antigen. Very definite agglutinations were noted towards the end of the second week after the commencement of the disease, and the titre rose rapidly and remained high during the long convalescence.

Prognosis.—This appears to be of about the same order as that in Malta fever. The disease is not fatal, but causes a long period of inability to work.

Treatment.—No account is given of any attempts to confer immunity, either prophylactic or phylactic, and the treatment would appear to be one aiming at rest, with measures to counteract the anæmia that tends to supervene.

SCARLET FEVER

Synonym.—Scarlatina.

Definition.—An acute specific fever of sudden onset characterised by faucial inflammation, a punctate erythema of the skin, and a tongue at first furred but later raw with prominent red papillæ. Desquamation follows, and inflammatory sequelæ may occur, involving especially the ears, cervical glands and kidneys.

Ætiology.—Scarlet fever is a disease of temperate climes and seldom gains a foothold in tropical or subtropical countries. It is endemic in large cities and populous centres, tending to flare up every few years in local epidemic form owing to the accumulation of susceptible subjects. Its general epidemic prevalence, however, is irregular, and no definite periodicity has been recognised. In the United Kingdom it is prevalent in the latter part of the summer and reaches its maximum at the end of the autumn; the period of least prevalence being the spring. Of late years, although the incidence has not appreciably declined, the mortality has fallen and the type of case become less severe. Severity, however, has always varied greatly at different periods and in different regions.

The case mortality of scarlet fever (proportion of deaths to attacks) is now not more than 0·5 or 2 per cent. It is greatest in the first year of life and diminishes with age. Females are more liable to infection than males, but attacks in males are rather more likely to terminate fatally.

Of predisposing causes, childhood and the absence of acquired immunity are the most important. Infants under one year of age seldom contract the disease, but mother and new-born infant may share the infection together.

The maximum incidence occurs during the fifth and sixth years of life, a period slightly later than is the case with such diseases as whooping-cough and measles. Adults are not exempt, but scarlet fever is rare in the aged. There is a tendency in some families to take the disease in a very severe form. As a rule, one attack protects permanently, but second attacks do undoubtedly occur. Multiple recurrences should probably be attributed to some other cause than scarlet fever.

Poverty, by entailing shortage of food, overcrowding, and defective isolation facilitates the spread of the disease and augments its death-rate.

The infective agent resides in the mucous secretions of the nose and throat and in the secondary suppurative lesions. The disease is infectious from its commencement, but the exact duration of infectivity cannot be determined for any given case. Six weeks' isolation is generally sufficient if by that time the mucous membranes are healthy and the skin free from sores. Many authorities reduce this period to 4 weeks for mild and uncomplicated attacks. Desquamation is not regarded as dangerous unless the scales are contaminated by the patient's discharges, and the infectivity of urine which remains albuminous has never been proved. The infectivity of scarlet fever is not nearly so great as that of measles, varicella or small-pox.

In most cases infection is by droplets derived directly from a person suffering with, or recently recovered from, the disease, but transmission by infected fomites or infected milk may also occur. Aerial infection by dust is possible, and dust from floors and blankets may possibly be a vehicle. It is an important fact that discharges from the nose, throat, mouth and ear may remain infectious for many weeks, and pre-existing purulent discharges also become infectious when scarlet fever is contracted. The occurrence of catarrhal infection of the nose or throat in a scarlet fever convalescent may lead to a recrudescence of infectivity.

Intermediary carriers have on occasions spread the disease without themselves showing signs of infection. On rare occasions, too, convalescents, although apparently healthy, have for months remained capable of transmitting the fever. The infectivity of carriers appears to be intermittent, and the receptivity of those exposed is increased by close and prolonged contact, debilitating circumstances or acute disease, of which diphtheria may be cited as an example. Attendants on scarlet fever cases, although long immune, may finally contract the disease.

Infected milk may be responsible for localised and, sometimes, for more widespread outbreaks of the fever. In most instances the milk has been infected from a human source, in kitchen, dairy or farm, but possible derivation of infection from cows with ulcerated udders and teats is suggested by the well-known Hendon outbreak. Scarlet fever is not known to be transmitted by water or by sewage. Cases of wound infection are not numerous, but puerperal scarlet fever is well recognised.

Pathology.—Klein, in 1887, isolated a streptococcus from the teats and udders of cows at Hendon, and considered it the causal agent in a milk-borne epidemic of scarlet fever. It became customary, however, to regard the streptococci found in the throats and tissues of scarlatinal cases as secondary invaders, it being impossible to grow these organisms from the blood of patients suffering from the fever in its toxic, and presumably uncomplicated form.

Drs. George and Gladys Diek, of Chicago, however, in 1923 produced evidence that scarlet fever is a *local* infection of the throat by a hæmolytic streptococcus, and attribute the general symptoms of the disease to erythrogenic toxins absorbed from the local focus. They infected patients with scarlet fever by swabbing the fauces with a pure culture of their organism and elaborated a test analogous to the Schick test in diphtheria. This is the *Dick test*. It is made by the intradermic injection of 0.1 c.c. of a 1 in 1000 dilution of toxic broth filtrate in saline solution. Boiled filtrate is used as a control. An erythema at the point of injection, maximal in 24 hours, indicates susceptibility to scarlet fever. The same types of reaction occur as in the Schick test (*q.v.*) but in the Dick reaction the erythema is not indurated. During the first few days of scarlet fever a positive result may be expected, but the test may prove negative for some days after the administration of anti-scarlatinal serum. A few convalescents remain positive to the test, the majority become negative. The new-born infant of a susceptible mother is usually Dick-positive. It is, however, noteworthy that a large percentage of Dick-positive individuals, although harbouring the bacilli, escape the disease.

Griffiths has shown by agglutination that the hæmolytic streptococci of scarlet fever are members of a group comprising many different serological strains.

Susceptible persons can be immunised by subcutaneous injection of increasing doses of scarlatinal toxin at intervals of 7 days. For adults four or five injections are required, commencing with 500 "skin test" units and ending with a dose of 50,000, 80,000, or even 120,000 units. The skin test unit of scarlet fever toxin is the smallest amount which gives a standard positive reaction in persons susceptible to scarlet fever, and a negative reaction in persons immune to the disease. The standard reaction is the appearance within 24 hours of an area of erythema not less than 1 c.m. in diameter. If too large an initial dose of immunising toxin is given, a transitory "miniature scarlet fever" may result, but this is rare. The simultaneous injection of 2 or 3 minims of 1 : 1000 adrenaline chloride solution prevents serious reactions. Immunity develops more slowly than in the case of diphtheria, and its duration is indefinite but prolonged. If the Dick test proves positive 6 months after, a further injection is recommended in the case of those nursing scarlet fever.

By immunising horses, an antitoxic serum is produced, which may bring about a rapid amelioration of the toxic symptoms of scarlet fever, but has little influence in preventing complications.

Schultz and Charlton pointed out that intradermic injection of 1 c.c. of the serum from a patient convalescent from scarlet fever will, in a few hours, cause a local blanching of the rash of the fever. This is known as the *blanching test*. W. Mair suggests that the test is due to antitoxic immunity in the donor, which will account for its occasional failure, and also the fact that the serum of some donors not known to have had scarlet fever, will give the reaction. The antitoxin prepared from the Dicks' scarlatinal streptococcus possesses the same blanching property, and now is used for the test.

The post-mortem appearances in scarlet fever are not distinctive. The rash, unless hæmorrhagic, disappears after death. Such gross changes as are found in the fauces, cervical glands, lungs, heart, kidneys and liver, together

with moderate enlargement of the spleen and lymphoid structures, merely indicate an acute infective process. In severely toxic cases, early decomposition with much post-mortem staining of the tissues, fluidity of the blood and subserous ecchymoses, indicate the intensity but not the nature of the infection. In cases surviving longer, inflammations of the lungs, serous sacs, endocardium, pericardium and joints may possibly be present, and desquamation may be recognised. Scarlatinal nephritis is essentially, but not exclusively, glomerular in type.

Symptoms.—The incubation period is short, the period which elapses between infection and the development of the first symptoms being from 2 to 4 days, with an average of 72 hours, or 4 days from infection to rash.

Invasion is abrupt, the cardinal symptoms being vomiting, headache and sore throat. In some severe cases vomiting may be so urgent as to suggest irritant poisoning, especially if accompanied by diarrhoea; in mild cases vomiting may be absent. Rigor is uncommon, convulsions occasionally occur in children. Cough and catarrhal symptoms are decidedly rare, but a mild conjunctival injection is not unknown. The skin is hot and dry, the cheeks flushed, and the eyes bright. The limbs ache, the appetite is in abeyance, and the tongue rapidly becomes coated with white fur, through which the papillæ project as red points (*strawberry tongue*). Slight nocturnal delirium is common. The temperature rises rapidly, and even on the first day may reach 103° or 104° F. An undue acceleration of the pulse is usually a marked characteristic, rates of 160 or more are common in young children, and rates of 120 to 140 in adults.

Very mild cases often occur, and in these the symptoms of invasion may be absent, the rash being the first indication of the disease.

Uniform injection of the tonsils, fauces, and uvula is present in the early stages of the disease. Later, the injection becomes more vivid, the tonsils are swollen, and a distinct follicular exudate often appears; inflammatory oedema of the fauces soon makes its appearance in severe cases, and may be accompanied by free mucous secretion. The tonsils may become covered by a thin necrotic film, or a more or less coherent exudate may form which may encroach on the faucial pillars and base of the uvula, and closely simulate the membranous exudate of diphtheria. In the more severe forms of scarlet fever, the tonsillar and faucial inflammation is very intense, and both ulceration and sloughing occasionally occur; thick muco-pus trickles down from the naso-pharynx, the nasal sinuses are invaded, and acrid discharge blocks the nostrils and excoriates the upper lip. The respiratory obstruction is especially severe if adenoids are present. In severe cases, inhalation bronchopneumonia is a decided danger.

A punctate injection may often be seen on the soft palate and adjacent part of the roof of the mouth even before the appearance of rash on the skin, and is diagnostic. The skin eruption usually appears within 24 hours of the invasion, but may be delayed sometimes for several days. It appears first on the upper part of the chest, the root of the neck and the upper arms as a finely punctate erythema; sometimes it is first seen in the axillæ. It quickly spreads to the trunk and limbs, reaching the legs last. The cheeks are merely flushed, and the existence of an area of circum-oral pallor is a well-known and striking feature. The thick skin of the palms and soles is also in most instances free from the distinctive rash. The eruption often shows a

symmetrical intensification in certain regions, such as the lower abdomen and groins, the inner aspects of the thighs, the axillæ, the back, and the points and flexures of the elbows and knees. Pressure produces a transient blanching.

Of the two elements of the rash, one is minutely punctate, the other erythematous. It is the former which gives it its distinctive character. On coarse skin the puncta are particularly large. When the erythematous element is intense the skin may actually appear cedematous and the puncta be quite obscured. In such cases, on subsidence of the rash, yellow staining may be apparent. In addition to punctation and erythema, minute petechiæ or small linear hæmorrhages are sometimes seen in the flexures of the elbows (*Pastia's sign*), groins, wrists and knees. By application of a tourniquet to the upper arm, petechiæ may be rapidly produced at the flexure of the elbow. This is the *Rumpel-Leede phenomenon*. It may also be positive in measles, small-pox, typhus, purpuric states and peliosis rheumatica. The linear hæmorrhages in the flexures remain when the rash has faded, and together with coarse injected papules on the outer sides of the arms and legs afford valuable diagnostic evidence. The rash on the buttocks and extremities may assume a slightly blotchy papular appearance, and so bear a distant resemblance to that of measles. Minute sudamina sometimes accompany the rash, giving rise to the variety known as *scarlatina miliaris*. Itching is not common, and urticaria is rare, but in some cases accompanies or precedes the outbreak of the rash.

The rash may be quite transitory or may last a week or even longer. Generally speaking, it is more pronounced in severe attacks, but sometimes attacks which are quite mild show rashes of considerable intensity and persistence. A dusky, blotchy, morbilliform eruption, generally limited to the convexity of the knees and elbows, but sometimes more widespread, may supervene in grave cases. It is known as the *septic rash*.

At the time of the initial faucial inflammation the lymph glands at the angles of the lower jaw are swollen and tender. During the eruptive period a moderate enlargement of the axillary and inguinal glands, sometimes of the posterior cervical glands as well, is often to be detected. The spleen is rarely to be felt. At times the glandular swelling leads to confusion with rubella, but the glands do not attain the size or show the marked localisation and tenderness characteristic of this disease.

In an average case a rapid rise of temperature (Fig. 1) marks the invasion, but the maximum may not be attained until the full development of the rash on the third or fourth evening, when readings of 103°, 104° or even 105° F. may be registered. Slight morning remissions occur. The fall is by lysis, reaching the normal by the fifth or sixth day of the disease. Termination by crisis is unusual. In bad cases of a septic type, the fever is prolonged, with increasing daily oscillations as septicæmic symptoms become prominent. In the malignant or toxæmic type of the disease, the fever is higher from the first and shows less remission, but occasionally is ominously subnormal throughout. A protracted remittent fever may occur in scarlet fever without local symptoms or complications to account for it; this variety is sometimes known as the "typhoid type." It is septicæmic in origin.

Abrupt rises of temperature during the convalescent period may signalise the onset of such complications as adenitis, otitis, nephritis, endocarditis, empyema, or a metastatic abscess. Sometimes such pyrexial

attacks occur without ascertainable cause, but a thorough examination of the patient is always necessary. Very mild cases of scarlet fever without obvious febrile disturbance certainly exist.

Desquamation is characteristic, but the degree to which it occurs is very variable. The tongue peels in patches or strips, and by the fourth day is raw with prominent papillæ (*raspberry tongue*). The flushed cheeks begin to shed a fine powder during the febrile period. Fine peeling of the lobules of the ears, of the margins of the lips, and of the skin at the root of the neck, possibly also above the pubes, next makes its appearance. By the end of the first week, peeling is generally well marked on the neck, chest, inner sides of the arms, and possibly on the trunk. Within a fortnight it may be seen on the hands and possibly on the feet. It may not be complete on the latter until over 6 weeks from the onset of the fever. Partial red-desquamation often occurs on the soles and is not infectious. The characteristic of the desquamation is the pinhole or ringed form in which it commences, the horny layers of the skin being shed first over the summits of the papillæ, forming apertures which enlarge centrifugally and fuse with their neighbours. Where the skin is thick, as on the hands and feet, it tends to separate in larger flakes, or may even be thrown off in the form of incomplete casts. A characteristic form of peeling is sometimes seen on the finger-tips when separation begins, as a split parallel to the free edge of the nail.

FIG. 1.—Simple scarlet fever. Showing abrupt onset and rapid lysis.

In severe cases considerable loss of hair may accompany or follow desquamation, but is temporary only, at all events in the younger patients. Furrows may also appear across the nails and take several weeks to reach the free edge.

Although desquamation typically proceeds as described above, there are cases of true scarlet fever where it is insignificant. It is unsafe to pronounce definitely against scarlet fever until 3 weeks have elapsed. In doubtful cases the hands and feet should be watched with care. A change to negative in the Dick test is confirmatory. A dry powdery appearance of the palms and soles is sometimes the sole indication of peeling. During desquamation the skin may appear harsh, dry, cracked or even eczematous.

A polymorphonuclear leucocytosis makes its appearance shortly after infection and reaches a maximum with the full development of the rash. It persists a variable time. In severely toxic cases it may fail to appear. A unique feature in favourable cases is an increasing eosinophilia during convalescence: this may even reach 10 per cent. Fluidity and slow coagulation of the blood are indications of severity, but apart from this blood examination has little prognostic value. Döhle has described certain bodies seen in the polymorphonuclear leucocyte when stained by Leishman's method as being characteristic. They appear in the acute stage as more or less definite blue spots in the cytoplasm of the cells. They are, however, not exclusively found in scarlet fever.

VARIETIES.—These are: (a) Simple or Benign; (b) Septic or Anginous; and (c) Toxic or Malignant. Surgical or Wound Scarlet fever and scarlet fever occurring during pregnancy or the puerperium, also have special characteristics.

Simple scarlet fever is characterised by an onset of moderate severity in which the initial vomiting is not repeated and sometimes is absent. The faucial inflammation is slight, and the temperature, which may reach 102° F., has almost reached its acme in 24 hours; generally the climax is reached by the third day and amelioration of symptoms is then rapid. The urine may be normal throughout, or a trace of albumin may accompany the febrile disturbance. By the third or fourth day the tongue, at first slightly coated, has peeled, and slight powdering may be evident on the cheeks. Convalescence is rapid.

The *septic or anginous* variety comprises most of the severe and fatal cases. It is characterised by intense faucial inflammation and a tendency to the development of septicæmic manifestations. Repeated vomiting, sharp diarrhoea and prostration may signalise the onset. The faucial inflammation is either severe from the first or unexpectedly becomes so after a lapse of 2 or 3 days. The tonsils are much swollen and a patchy or coherent membranous exudate may form. Rapid and destructive ulceration of the tonsils, soft palate and its pillars sometimes occurs. The mucous membrane of the mouth may be excoriated and bleed at the slightest touch. The pharynx, and even the upper aperture of the larynx, may become involved in the inflammation, although, as a rule, implication of the latter is more suggestive of diphtheria than of scarlet fever. The discharges from the throat excoriate the angles of the mouth and a purulent acrid rhinorrhoea irritates the nares and upper lip. Deglutition is painful, respiration is obstructed, and the patient often sleepless, restless and later delirious. The cervical lymph glands become swollen and tender, and peri-adenitis or extensive sluggish cellulitis of the neck may ensue. This sometimes gives rise to fatal hæmorrhage by eroding large veins or even an artery. Cyanosis and coldness of the extremities and cardiac dilatation are common. The rash is generally intense, dusky and blotchy. The temperature often reaches 104° or 105° F. in the early stages of the disease, and pyrexia may persist long beyond the ordinary period and, changing its type, assume a remittent or intermittent septicæmic form.

Death may occur in the first week; more often life is prolonged into the second week, by which time circulatory failure becomes pronounced; hypostatic congestion of the lungs or spreading broncho-pneumonia occurs.

Otitis, arthritis, suppurations of the serous sacs, endocarditis, or nephritis may appear as complications, and a true scarlatinal pyæmia be evident. (Fig. 2.)

Many patients show septic symptoms of a much milder type and make good recoveries. In grave cases which recover, improvement is very gradual and usually sets in towards the end of the second week, but may be later.

Toxic or malignant scarlet fever is characterised by a toxæmic condition out of all proportion to the degree of inflammatory reaction in the throat. Such cases are marked by high fever, cerebral disturbance, profound prostration and circulatory failure. The rash is often petechial, but in the most severe attacks the patient may die before it has time to appear, and the real nature of the disease may only be revealed by the supervention of scarlet fever in contacts. The throat may be intensely injected, but the œdema, ulceration and thick purulent secretion which characterise the septic variety may be absent altogether. Sometimes convulsions precede death, but mostly

FIG. 2.—Temperature chart in case of scarlet fever with pyæmia.

delirium merges into coma. Rarely, however, the patient dies of circulatory failure with vomiting, prostration and extreme pallor, but with clear intellect, suggestive of the type of death seen in some cases of diphtheria.

Sufferers from the malignant type of scarlet fever mostly succumb within a week of the onset, sometimes within 24 hours. But, as in the septic form, cases of the toxic or malignant type are not now so common or characterised by such extreme malignancy as was formerly the case.

Rarely scarlet fever assumes a purpuric form, with bleeding into the skin and sometimes from the mucous membranes also. This complication makes its appearance towards the end of the second or during the third week, and often proves fatal. It is possible that some of the cases formerly described as scarlatinal, where hæmorrhages occurred early in the eruptive stage of the disease, were really hæmorrhagic small-pox with prodromal rashes of scarlatini-form character.

Surgical scarlet fever may be a sequel of operations, wounds or burns and scalds. It is often seen after operations on the nose and throat. The incubation period is short, often less than 3 days, and the rash may make its first appearance round the wound. Faucial inflammation save in throat cases

is often slight, and faucial swabs may be negative. The infected wounds show a great tendency to suppurate. When the infection starts from a wound or abrasion on a limb, injected lymphatic vessels are often evident which show a characteristic punctate rash along their course. The corresponding lymph glands are enlarged and tender. The infected lesion may be small and is often overlooked, but the discovery of lymphangitis in a scarlet-fever patient should always arouse suspicion that the infection is of this type. When the fever follows burns or scalds the incubation period is also short and the accompanying angina may be slight. Cases of surgical and of burn scarlet fever where the throat is not especially involved are not highly infectious. They are often left in general wards with impunity, but there is no doubt that occasionally they spread the infection.

Scarlet fever may arise in the pregnant woman. In early pregnancy it is rare, and is said not to lead to abortion; but occurring later it is very prone to produce abortion or premature delivery. When the infection occurs either immediately before or immediately after labour, it is apt to assume a grave form with a very high mortality from septicæmia; but there is no doubt mild attacks may occur even at this period.

Anomalous forms of scarlet fever occur in which one or more of the cardinal symptoms are lacking. In some only sore throat is recognised (*Scarlatina sine eruptione*), and yet the patient may transmit the typical disease. The cases of infectious sore throat which often herald outbreaks of scarlet fever belong to this category. In these patients there is immunity to the erythrogenic toxin but antibacterial immunity is lacking. In others the rash is so ephemeral or atypical that its true nature escapes recognition; in yet others, the rash is the most pronounced feature, both fever and sore throat being insignificant. In cases where the rash is very scanty or insignificant and also after antitoxin treatment, desquamation may not be at all marked.

Complications.—These fall into two groups: those which arise locally in connection with the faucial and pharyngeal inflammation, and those of a general or more remote character. To the first group, in order of frequency, belong otitis, cervical adenitis, rhinitis, secondary tonsillitis and stomatitis, and aspiration broncho-pneumonia. The second group includes rheumatism, albuminuria, nephritis, endocarditis, inflammations of the serous sacs and metastatic abscesses. In severe cases complications show a great tendency to occur in combination rather than singly.

Otitis.—This is met with in from 10 to 15 per cent. of the cases, and is an inflammation of the whole mucous tract of the middle ear. Its greatest frequency is in childhood, and its incidence is favoured by the presence of adenoids. It is more common in severe cases, and may show itself by the end of the first week of the fever or later. It is often bilateral. Earache with an injected and bulging tympanic membrane are the signs to be expected, but sometimes a free discharge of mucus or pus and blood from the ear is the earliest indication. Unexplained pyrexia not due to fresh faucial or glandular extensions or to one of the distant complications should always lead to a careful examination of the ears. Perforation generally occurs in the upper part of the tympanic membrane. Deafness may occur, but fortunately is transient in most cases. Pain and tenderness with slight oedema of the mastoid appear in some instances, and may be accompanied by restlessness,

vomiting and fluctuating temperature. The intensity of these mastoid symptoms may vary from day to day. In children the mastoid air cells are very superficial, and pus easily makes its way beneath the covering periosteum.

Sometimes the labyrinth becomes implicated. In such cases deafness, vomiting, vertigo and nystagmus may occur. Labyrinthine deafness may be permanent.

Such intracranial complications as meningitis, extradural abscess, lateral sinus thrombosis, cerebellar or temporo-sphenoidal abscess, belong to the more chronic forms of ear disease, but occasionally they arise during the acute stage. Persistence of mastoid tenderness with some local headache and slight fever may be the only signs of inflammatory mischief invading the dura in the vicinity of the lateral sinus.

In most instances scarlatinal otitis subsides in a few weeks and the perforation of the membrane closes.

Secondary Adenitis.—A rapid and considerable swelling of the upper cervical lymph glands may occur during the convalescent stage of the fever. The swollen glands are usually those behind the angle of the mandible or higher up under the insertion of the sterno-mastoid muscle. The adenitis, the basis of which is a congestive oedema with reticulo-endothelial proliferation, generally supervenes during the second, third or fourth week of the disease. It is marked by local tenderness and a sharp accession of fever. In favourable cases the temperature becomes normal in a day or two and the glandular swelling rapidly subsides, but suppuration may ensue.

Secondary tonsillitis should suggest the possibility of diphtheritic infection. Peritonsillar abscess may occur. Ulcerative stomatitis with much fetor of breath and sometimes even sloughing of soft tissues and necrosis of bone are also looked upon as secondary infections. Vincent's organism and diphtheria bacilli should be sought for in such cases.

Rhinitis.—Acrid or purulent rhinorrhœa is characteristic of septic attacks. The air sinuses may become infected. A rhinorrhœa which occurs in the later stages of the fever is often responsible for the transmission of infection. True diphtheria bacilli are more frequently found in the nasal than in the ear discharges of those suffering from scarlet fever.

Nephritis.—Slight albuminuria during the eruptive stage of scarlet fever is transitory and of no great importance, but about the third week nephritis may supervene. Authorities variously place its incidence at from 3 to 8·4 per cent. The condition is toxæmic. Streptococci are not present in the urine. It is more common in severe than in mild attacks. Chill, damp and exposure favour its incidence. The onset may be insidious or fulminant. In the insidious cases albuminuria, at first slight, and even intermittent, is the first sign. In the fulminant cases, headache, vomiting, pyrexia and even rigor may mark the onset. The urine becomes heavily loaded with albumin, casts and blood, and there is more or less suppression. The temperature may rise gradually or suddenly and show marked daily remissions. Lumbar pain is uncommon, but abdominal pain and constipation are marked features of some attacks. The amount of dropsy is very variable; it may be considerable in ambulant cases. Anæmia is of rapid onset and very pronounced. The pulse tension is raised and cardiac hypertrophy is soon established, sometimes dilatation ensues. In a favourable case some improvement occurs within a week, the secretion of urine increasing, but the hæmaturia and

albuminuria take much longer to clear up. In some cases albuminuria persists and chronic interstitial nephritis may ensue. The duration of an average attack may be put at 7 weeks, but is subject to much variation. Broncho-pneumonia, pulmonary œdema, œdema of the glottis, and uræmic symptoms occur in severe cases. Convulsions may be recovered from, but coma is of bad augury.

In the septic type of scarlet fever sharp hæmaturia with casts and streptococci may accompany other pyæmic manifestations.

Rheumatism.—This is common, and usually makes its appearance towards the end of the first week. The arthritis is fleeting and mostly involves the hands and wrists. Joint effusions are not always present. The temperature is raised. Sometimes the endocardium and pericardium are implicated, as in ordinary rheumatism, but the profuse sweats and creamy tongue are absent. Scarlatinal rheumatism is more common in adolescents and adults than in children. A mono-articular or multiple suppurative arthritis with, it may be, other pyæmic manifestations is sometimes seen and is generally of later onset.

Cardiac complications.—There are three groups: those due to toxæmia; those secondary to rheumatic or pyæmic complications; and those accompanying nephritis. The toxæmic effects are cardiac dilatation and acceleration of the pulse, which are so characteristic of this fever.

Scarlatinal rheumatism is occasionally the precursor of simple or more rarely of malignant endocarditis. An unfortunate feature is the tendency to pick out the aortic valves. The influence of nephritis in producing rapid cardiac hypertrophy or inducing dilatation has already been mentioned. Pericarditis may occur quite early in some cases of the septic type. The effusion is generally purulent.

Pulmonary complications.—Neither bronchitis nor broncho-pneumonia is common, but aspiration broncho-pneumonia may complicate septic cases. Œdema of lungs may arise during the course of acute nephritis. Lateral sinus pyæmia may give rise to pyæmic infarction of the lungs, empyema and even pneumothorax. A primary empyema, often of insidious onset, occurs in some patients. Lobar pneumonia is rare; occurring early in the disease, it is streptococcal in nature and the prognosis is very grave.

Streptococcal peritonitis is a very rare event.

Nervous complications.—If the delirium of onset, the nervous manifestations of uræmia and the cerebral complications of otitis are excluded, it may be said that nervous disturbance during the course of scarlet fever is rare. In those predisposed, epileptic fits may signalise the invasion. Hemiplegia with convulsive onset, incomplete paraplegia and peripheral neuritis have all been described, but hemiplegia is more often secondary to uræmia or to a cardiac lesion than primary. Chorea develops occasionally, usually in association with arthritis and endocarditis. Tetany sometimes occurs. Mental disturbance of a maniacal or melancholic type is an infrequent sequel, or may show itself during the acute stages.

On rare occasions gangrene of the extremities has been encountered. It is sometimes embolic in origin and leads to mummification, but gangrene has also been described in association with purpura and in congenital syphilis.

Post-scarlatinal diphtheria was, in pre-antitoxin days, one of the gravest complications. Diphtheria may develop at the onset of the fever, but more

often appears during early convalescence. It occurs more often in hospital-treated cases than in others. Every throat inflammation about the nature of which there is the slightest doubt should be subjected to bacteriological examination at once. This is a more rational procedure than the indiscriminate injection of all scarlatinal patients with diphtheria antitoxin. All nasal and ear discharges should also be bacteriologically examined.

Relapse and Reinfection.—A recurrence of the fever and rash before complete recovery from the initial attack occurs in from 0.5 to 7 per cent. of those treated in hospital. In such cases it is not uncommon for the original infection to be replaced and protracted by one of different serological type.

Diagnosis.—Bacteriological identification of the *Streptococcus scarlatinae* is not sufficiently precise to afford much help in diagnosis. All that can be said is that the detection of *B. hæmolytic streptococci* in the nose or throat suggests scarlet fever and their absence the reverse. A positive Dick test before the third day of the attack is in favour of scarlet fever (it should become negative later) but a negative result does not exclude it. A positive Schultz-Charlton blanching test, made by the intradermic injection of 0.2 c.c. of a 1 in 10 dilution of immunised horse serum applied to the newly developed rash, preferably on the lower abdomen, is of more value. The reaction takes 8 hours to develop, and attains a diameter of 3 c.m. or more. Its value in the diagnosis of doubtful cases with ill-developed or fading rashes is small.

The chief diagnostic difficulty arises with mild attacks and with patients who come under observation after the initial stage. In the former the rash is evanescent, constitutional disturbance slight, and the tongue often atypical. A history of a previous attack is of great weight, but diagnosis can only be confirmed by the supervention of desquamation or of some characteristic complication. Sometimes the infection of a contact gives the clue. In days immediately following the rash significant signs are: slight staining of the trunk, faint striæ in the flexures of the elbows, knees and groins, or a triangular patch of punctate erythema over Scarpa's triangle. The submandibular glands may be enlarged, and coarse papules resembling goose-skin present on the outer aspects of the arms and legs. The tongue has usually peeled by the fourth day and remains raw and papillated for about a week. Slight albuminuria, in the absence of diphtheria, is significant.

Desquamation of the typical pinhole type rarely occurs in other conditions than scarlet fever; the character of the accompanying symptoms and the time of appearance of the peeling must be taken into consideration.

Simple tonsillitis is distinguished by the absence of punctate rash, a tongue which does not peel but remains heavily coated, and absence of desquamation. But an erythema may be present, with fleeting muscular pains and sometimes otitis, and even endocarditis or nephritis may occur as complications. Where immunity to the erythrogenic toxin is complete, scarlet fever may present itself as a streptococcal tonsillitis the rash being absent.

Careful scrutiny of the body for a rash will usually prevent confusion with *diphtheria*. When faucial exudate is present in scarlet fever, it is usually softer and less coherent than in diphtheria, and any grey ulcerated areas are depressed below the general surface. In scarlet fever, too, the faucial pillars and palate may show the punctate rash, whilst pallor of the throat is more distinctive of diphtheria. In scarlet fever, febrile disturbance is more

marked, initial vomiting is common, and delirium may occur. The fugitive erythema which sometimes appears on the chest in diphtheria is not punctate. Bacteriological examination is decisive in diphtheria, but the two diseases may coexist.

When *influenza* is rife, cases of scarlet fever are apt to be overlooked ; but in *influenza* rashes are exceptional, and careful observation of the progress of the disease will soon lead to a correct diagnosis.

Lobar pneumonia may, in children especially, by its abrupt onset, high fever, vomiting and faucial inflammation, give rise to suspicion of scarlet fever, a suspicion favoured by the flushed face and circumoral pallor which may be present. But the throat affection is trivial, the respirations are rapid and accompanied by action of the *alæ nasi*, and there is no punctate rash on the chest. Sooner or later consolidation of the lung may be detected, often in such obscure cases at the apex or high in the axilla.

Food, drug, serum and enema rashes often cause difficulty. Of drugs the most important rash-producers are copaiiba and similar oleo-resins, quinine, phenazone, the salicylates, aspirin and belladonna. Arsphenamine compounds gold salts and sulphonamides may also do so. Anomalous distribution or polymorphic character of the rash should at once arouse suspicion, especially so the discovery of urticarial wheals. Fever, slight generalised adenitis, enlargement of the spleen and leucopenia are recognised accompaniments of some drug rashes.

Erythema scarlatiniforme is characterised by a punctate eruption which is sometimes patchy and confined to the trunk. The rash is remarkably persistent, and desquamation may ensue whilst it is still in the florid stage. The peeling is profuse and the subjacent skin often erythematous. The characteristic sequelæ of scarlet fever are wanting. The disease is not known to be infectious and is very apt to recur, which gives a clue to its recognition. *Acute exfoliative dermatitis* is by some regarded as identical.

German measles in the scarlatiniform stage closely resembles scarlet fever. The diagnosis turns on the trivial character of the accompanying symptoms, which are chiefly catarrhal, and the tender swelling of the posterior cervical, mastoid, and occipital glands. Even when the rash is scarlatiniform on the trunk, distinct morbilliform elements may often be recognised about the wrists and on the lower extremities, and this, with the history of an initial spotty rash on the face and around the mouth, is of great significance. The eyes are suffused and subsequent desquamation is insignificant. Sequelæ are practically unknown.

Measles is more easily distinguished. The rash is different and invades the face. Catarrhal symptoms are pronounced and Koplik's spots are present. Difficulty is only likely to arise in those cases of scarlet fever where a blotchy rash is present, or where the appearance of a septic rash may simulate inter-current measles.

Prodromal rashes of a scarlatiniform type may appear in small-pox, chicken-pox and measles. In small-pox, the punctate rash is usually confined to the bathing-drawers area and to the axillæ. Sore throat is in favour of scarlet fever, whilst rigor and severe lumbar pain suggest small-pox. The eruption of the latter disease appears on the third day, and a doubtful case should always be isolated over that period. The initial rashes of small-pox are said to be absent in children under 10 years of age.

The eruption of chicken-pox may be heralded by a rash which is scarlatini-form, but it is more likely to be erythematous. The diagnosis turns on the condition of the fauces and tongue, the absence of other signs of scarlet fever, and the speedy appearance of vesicles on the palate and the trunk.

As a prodromal rash in measles, a scarlatiniform eruption is rare. The catarrhal symptoms which accompany it will arouse suspicion, which is confirmed by the discovery of buccal inflammation and Koplik's spots.

Prognosis.—The mortality of scarlet fever varies with the type of the prevailing epidemic. Of late years, in Great Britain, a mortality of less than 1 per cent. has been the rule. Of other factors, age is the most important, the mortality being greatest in infancy, diminishing rapidly after the second year, and continuing to fall until puberty is reached, the least fatal period being from puberty to 36, after which age a slight rise occurs. The death-rate is slightly higher in males than in females. Tuberculous infections are apt to be lighted up, and puerperal patients run a grave risk of septicæmia. Chronic renal disease is likely to be adversely influenced.

Malignant attacks are very fatal, and the septic type of attack is also serious, especially if broncho-pneumonia supervenes. In adults, sleeplessness and delirium are unfavourable signs, and in children, convulsions occurring after the initial stage. Nephritis in many instances clears up, especially if detected early and properly treated. Grave symptoms are uræmic convulsions, coma, repeated vomiting and suppression of urine. Œdema of lungs often precedes the fatal issue.

Of other complications, pericarditis is the worst. It is often purulent and may be associated with empyema. Hemiplegia, if of vascular origin, mostly becomes permanent. The danger of otitis media is remote rather than immediate.

Treatment.—**PROPHYLACTIC.**—Infectivity ceases mostly within a period of 4 to 6 weeks, but is apt to be prolonged in the presence of complications. A negative throat culture does not always indicate cessation of infectivity, and this test is not employed as a routine measure. Late desquamation of the hands and feet is not a source of infection, but discharges from the nose, throat or ear are dangerous. Convalescent carriers are responsible for something less than 3 per cent. of the cases treated in fever hospitals. The dangerous carrier is often characterised by unhealthy conditions of the nose, throat or ear, discharges from which may have reappeared owing to the supervention of catarrh. Patients with persistent tonsillitis, adenitis, rhinorrhœa or otitis should be isolated for at least 12 weeks from the commencement of the fever. The discharge of patients direct from wards containing others in the acute stage of the disease should be avoided; isolation for a day or two in a separate apartment is advisable. It is safer to remove those who remain Dick-positive during convalescence from all contact with acute cases. In cold weather the practice of bathing on the very day of discharge is not recommended, as a catarrh may be thus induced. Patients should not pass straight from isolation into the company of children and other susceptible persons. Thorough disinfection of the sick-room and all its contents is essential.

Individuals in close contact with scarlet fever although themselves immune, have at times been found to convey the infection (*immune carriers*), but a greater source of danger is the convalescent carrier, whose infectivity

persists beyond the usually recognised period. The infectivity of such carriers has been known to last for weeks and even months ; there is some evidence that it is intermittent.

The rules originally formulated by the Medical Officers of Schools may be taken as a safe guide in practice, *i.e.* isolation for not less than 6 weeks, provided convalescence is complete and there is no evidence of inflamed throat or of discharge from the nose or ear, no suppurating or recently enlarged glands, and no eczematous patches about the nostrils, mouth or elsewhere. For very mild attacks, however, 4 or even 3 weeks in hospital followed by 2 weeks' convalescence is sufficient. The quarantine period for contacts is 10 days, provided disinfection was efficiently carried out at the commencement of that period, but often this is not enforced in the case of healthy adults no longer exposed to infection. In institutional and ward outbreaks the contacts should be Dick-tested for susceptibility and throat swabs examined for hæmolytic streptococci. Those who harbour streptococci should be isolated. The susceptibles in ward outbreaks usually receive 5 or 10 c.c. of antitoxin, which establishes a temporary passive immunity. But the same procedure as recommended in diphtheria (p. 109) is probably better.

CURATIVE.—Doubtful cases should be isolated until a definite diagnosis is made. Their premature transfer to a scarlet-fever ward is unjustifiable. Isolation of scarlet fever at home is most successful when a whole floor can be set apart for the patient and attendants, and there are no children of susceptible age in the house. The sick room should be large, light, freely ventilated and adequately warmed, the temperature being maintained at 55° F. to 60° F. Overalls should be worn by attendants, and all articles used by the patient sterilised at once.

The action of the skin is promoted by a daily wash and a tepid sponge every evening during the pyrexial stage. This may be replaced by a daily warm bath when defervescence is complete. The bed coverings should be adequate, but not too heavy. During convalescence, flannel or wool is the proper clothing ; chill is to be avoided. During the febrile stage the diet should consist of milk, barley water, and weak tea. Water and fruit juices may be given freely, to counteract dehydration. When the temperature falls, beaten-up eggs and farinaceous food may be added and the diet gradually increased, nitrogenous food being allowed early in small amount. Most patients are fit for full diet within a week of the subsidence of the fever. Children, at all events, should be confined to bed for 3 weeks from the onset ; by this means chills are avoided, the usual period of onset of nephritis passed, and the throat healed before the patient gets up. When the weather is warm, outdoor exercise may be allowed with advantage in the third or fourth week.

Attention should be paid to the mouth, teeth and gums, since oral sepsis is believed to bring its own train of local complications. The bowels should be regulated with mild aperients.

In all but the mildest cases concentrated scarlatina antitoxin should be given early. The dosage varies from 6000 to 30,000 U.S.A. units according to severity and day of disease. The U.S.A. antitoxin unit is the amount which neutralises 50 "skin-test" doses of the standard scarlet fever toxin. Administration is repeated daily in severe cases if necessary. The serum is given intramuscularly. If the intravenous route is chosen, reactions may be very

severe, the serum should be diluted, and to guard against anaphylaxis, a preliminary intravenous test injection of $\frac{1}{10}$ c.c. in normal saline is advisable. Preliminary desensitisation is essential in sensitised patients (see p. 7).

Sulphonamide preparations are valuable in streptococcal complications such as otitis, but do not influence the toxæmia of the disease.

Osman states that the incidence of nephritis is diminished if sufficient alkali is administered to keep the morning urine alkaline.

Pyrexia, with restlessness, insomnia and delirium, may be controlled by tepid sponging and acetylsalicylic acid or paraldehyde. A cold pack at 60° or 70° F. for 15 or 20 minutes is beneficial when nervous symptoms are pronounced. After the middle of the second week, if albuminuria is present, cold sponging and cold packing should be avoided.

Persistent vomiting may be controlled by the use of diluted or citrated milk or temporary substitution of albumin water. Liqueur iodi mitis in doses of 3 or 5 minims in water is often efficacious. When swallowing is painful the feeds should be small and often repeated.

For the local treatment of the throat and nose, gargles are quite ineffective, and sprays have but little cleansing influence. Alkaline carbolic or hot saline lotions should be applied by gentle syringing or through a douche-can under low pressure. The syringe nozzle, which should be short, is passed into the mouth behind the back teeth, the patient lying on the side with the head low. It may be necessary to envelop children in a large towel which secures the arms. For very septic and offensive throats a free chlorine lotion should be used every 2 or 3 hours. It is made by putting 200 grains of potassium chlorate in a large dry bottle, pouring on it 40 minims of strong hydrochloric acid, and setting aside, loosely corked, for 10 minutes; a pint of water is then added in 4 or 5 successive portions, shaking well. An equal quantity of water should be added to this solution before use. Great gentleness should be exercised if the nose is syringed; it is generally unnecessary. Ointment should be applied to the nares and upper lip to prevent excoriations.

Secondary tonsillitis is treated on ordinary lines, but care must be taken not to overlook diphtheria. One-sixth grain of calomel dissolved on the tongue half-hourly for six doses, repeated if necessary, is very effective. Cervical adenitis is treated by smearing glycerine on the neck and applying cotton wool. Poulticing is rarely called for; it appears to precipitate suppuration. Inflamed glands should only be incised when the presence of pus is assured. Care should be taken that the ears are clean. The pain of otitis may be mitigated by syringing with water as hot as can be borne and the application of hot, dry cotton wool, or a rubber hot-water bottle, to the side of the head. By some the instillation of a few drops of glycerin of carbolic acid and the use of fomentations are recommended. Incision of the tympanic membrane is the most efficient method. Discharging ears should be cleansed frequently with hydrogen peroxide and mopped dry with spirit but never plugged. After the fourth week of the fever, removal of adenoids and infected tonsils shortens the duration of discharge. Watch must be kept for mastoid tenderness and œdema.

Scarlatinal rheumatism is usually mild and transitory; salicylates, or acetyl-salicylic acid give relief. When joint swellings persist, a mild pyæmic condition is often present, and may be associated with endocarditis. Some advise a cautious trial of intravenous scarlatinal serum in such cases. When

the presence of pyæmic arthritis is suspected an exploratory aspiration under strict asepsis may be advisable. This may lead to subsidence.

Scarlatinal nephritis.—The importance of daily examination of the urine and avoidance of chill must be emphasised. No patient with albuminuria should be allowed up. During the acute stage of nephritis the diet should be limited to milk, fruit juices and barley water. In very acute cases, water only may be given for 24 hours or even longer. Later a low protein diet may be necessary. The patient should be clothed in flannel and lie in blankets. The bowels should be regulated with salines or compound jalap powder: constipation is often troublesome. Action of the skin should be encouraged by simple diaphoretics and the use of hot bottles, hot packs or an incandescent electric bath. Acetyl-salicylic acid is useful in promoting sweating. Thirty grains each of sodium citrate and bicarbonate should be given three times a day. For uræmia, free purgation and sweating should be induced; venesection is useful in older patients, coupled with saline infusion. Repeated uræmic convulsions call, in addition, for paraldehyde in olive oil per rectum, chloral or chloroform. Lumbar puncture may have a good effect. Morphine if given with caution may be useful in convulsive states. Blood pressure should be watched and blood urea estimated.

Grave circulatory failure calls for strict recumbency. Strychnine in doses of gr. $\frac{1}{16}$ every 2 or 3 hours is often used, best in combination with adrenaline and atropine (see p. 111). Nikethamide (coramine) leptazol (cardiazol) and diffusible stimulants such as ammonia and ether mixture, and brandy or champagne, are of value. Oxygen inhalation, hot saline by the bowel, or glucose enemata (5 per cent.) are useful accessories.

The most promising treatment for *hæmorrhagic scarlet fever* is blood transfusion, preferably from an immune donor, or free administration of liver extract. Vitamin K or vitamin C may possibly prove of use.

TYPHOID FEVER

Synonyms.—Enteric Fever; Gastric Fever; Typhus Abdominalis.

Definition.—An infectious fever characterised by pyrexia of distinctive type, an eruption of rose spots, enlargement of the spleen, abdominal tumidity with discomfort and bowel disturbance. Ulceration of the small intestine and enlargement of the mesenteric lymph glands and spleen are distinctive lesions. Typhoid is a septicæmia caused by ingestion of the *Bacillus typhosus* of Eberth, which is absorbed by the lymphatics of the small intestine and carried to all parts of the body; it settles in the agninate glands (Peyer's patches) of the intestine, the mesenteric lymph glands, spleen, liver, gall-bladder and bone-marrow. Those organs which have excretory ducts, e.g. the liver and gall-bladder and the kidneys, as well as the intestinal tract, form the chief channels of elimination.

Ætiology.—The *Bacillus typhosus* (*Eberthella typhi*) is a flagellated, rod-shaped organism, about 3μ in length and 0.6μ in thickness. It is actively motile and easily grown on artificial media. It belongs to the enteric group of organisms, a group which includes also the paratyphoid bacilli (*Salmonella typhi*). It grows best at blood heat and is quickly killed by boiling water, and within 15 minutes by exposure to a temperature of 60°C . (140°F). It

may survive for a considerable time in ice, and also in fresh or salt water. It resists drying, so that typhoid may also be propagated by dust or by articles soiled by typhoid excreta. It has been found alive in the mantle-cavity and intestines of oysters, mussels and other shell-fish which have lived in sewage-contaminated water. It multiplies freely in butter and in milk.

The toxins are mainly intracellular. Inoculation of animals produces a septicaemia without the intestinal lesions seen in man. Even in the latter the disease at times occurs without producing intestinal ulcers. The serum of patients has a specific agglutinative influence on cultures of the organism, a fact which is made use of in diagnosis, and at certain stages the bacillus can be cultivated from the blood. In man, infection is introduced by the alimentary tract, and is derived, directly or indirectly, from a human source, man being the only reservoir of the disease. Typhoid bacilli can be differentiated into types by the use of specific bacteriophages, a useful measure in tracing sources of infection.

Typhoid occurs in all parts of the world, but is most rife in tropical and subtropical countries. In Great Britain it is most prevalent in the months of September, October and November; in other countries the maximum incidence corresponds to the warm season. A hot, dry summer increases the prevalence in the autumn. An epidemic recrudescence is believed to occur every 5 or 7 years. Rather more males than females are attacked, and the greatest susceptibility is between the twentieth and twenty-fourth years. Infants are rarely infected. After the thirtieth year there is a progressive fall in its incidence. It is rare but not unknown in old age.

One attack confers immunity, which usually lasts for life, but second and third attacks have been reported. Where typhoid is endemic a proportion of the community acquires immunity without having passed through a recognisable attack. The supposed racial immunity of certain peoples may in reality be acquired through infection contracted in childhood. Fatigue and overwork are predisposing factors, and no condition predisposes so much as war to typhoid and paratyphoid infections, owing to the aggregation of susceptible subjects under conditions of defective sanitation, fatigue and exhaustion. Prophylactic vaccination has found its greatest triumphs under these conditions.

Propagation is from the human source and may be indirect or direct. Of indirect causes aerial infection, apart from the influence of wind-borne dust and of flies, is very doubtful. Drinking water supplies contaminated by sewage or by the excretions of a carrier are the most common cause of widespread outbreaks. Milk, unripened cheese, butter and other articles of food may also act as local diffusers of infection. Watercress and green vegetables, eaten uncooked, also spread the disease. Amongst shell-fish, oysters, mussels, cockles and periwinkles are dangerous. Fomites, enema syringes, bedpans, etc., which have been soiled by typhoid excreta undoubtedly act as infective agents. Laboratory workers have been infected by their cultures.

Direct contagion plays but a small part in the production of epidemics, but assumes importance in causing localised outbreaks, infection being conveyed by the faeces, the urine, the vomit, discharges from abscesses and possibly by the sputa. The chief danger arises with mild and unrecognised cases and precocious carriers (i.e. by infected susceptibles who have not yet succumbed to the disease). Strict attention to personal cleanliness and

proper disinfection of excreta, soiled linen, feeding utensils, etc., go far to eliminate infection, and prophylactic inoculation is a great safeguard.

Of convalescents from typhoid, a small proportion, about 5 per cent., continue to pass bacilli, perhaps intermittently, in the stools for months or years. These are known as intestinal carriers. They may appear to be quite healthy, or may suffer from periodic intestinal disturbance or from symptoms referable to the gall-bladder. Typhoid bacilluria occurs in perhaps 25 per cent. of the cases of typhoid, but is as a rule quite transitory, urinary carriers being much less common but possibly more dangerous than intestinal carriers. Carriers are particularly dangerous when they happen to be engaged in handling food, milk or water supplies.

The endemic occurrence of typhoid in certain localities is now attributed to the influence of human carriers rather than to the persistence of infection in the soil, although it is an undoubted fact that the typhoid bacillus may persist for a time and even multiply in sewage-infected earth.

Pathology.—The portal of infection is the intestinal lymphatic system. The bacilli multiply in the liver, spleen and mesenteric lymph glands during the incubation period. A bacteræmia initiates the clinical onset and excretion via the bile soon follows. It is now, contrary to former conceptions, held that the Peyer's patches are not involved until the septicæmic stage. The characteristic lesions are in the small intestine. Proliferation of the large mono-nuclear phagocytes of the reticulo-endothelial system is the distinctive reaction. In the early stages the Peyer's patches are swollen, the swelling attaining its height about the tenth day of the disease. The solitary follicles of the intestine are similarly affected and a diffuse catarrh of the whole intestinal tract, including the stomach, may be present. Necrosis ensues in the lymphoid masses, and sloughs are formed, the separation of which occurs during the third and part of the fourth weeks. In some cases, resolution may take place without necrosis. The ulcers are ovoid and lie along the long axis of the bowels. Those which arise in the solitary follicles are more circular. The edges of a recent ulcer are undermined, and the floor shows smooth muscular fibres, or the peritoneal coat. Perforation or hæmorrhage may ensue. Immediately above the ileo-cæcal valve sinuous tracts of ulceration may be evident. Ulceration of the large intestine is rare. The ulcers heal without contraction in a week or ten days. When perforation occurs it is usually in the lower ileum, where ulceration is most intense. It may, however, happen in other situations.

The mesenteric lymph-glands are inflamed, but rarely suppurate. The spleen is swollen, soft and red, an acute reticular hyperplasia being present. Splenic infarction may occur, but rupture is rare. The liver presents a parenchymatous degeneration with minute areas of focal necrosis which originate in clumps of macrophages lying in the blood sinuses. Infection of the gall-bladder may occur with subsequent formation of gall-stones. Pylephlebitis is a rare complication. Cloudy swelling of the kidneys is the rule, occasionally a parenchymatous nephritis ensues. In chronic urinary carriers inflammation of the renal pelvis or urinary bladder may be found.

The myocardium shows fatty and granular degeneration. Endocarditis is exceptional, but endarteritis may affect the aorta, coronary arteries and peripheral vessels, and arterio-sclerosis is a possible sequel. Hypostatic congestion of the lung bases is the rule with, it may be, distinct broncho-

pneumonic consolidation. Gangrene, abscess or infarction of the lungs is rare. Ulceration of the larynx may occur, the ulcers being found in the neighbourhood of the arytenoid cartilages, or at the base of the epiglottis. Necrosis of the cartilages sometimes ensues. Zenker's vitreous degeneration of muscle is particularly marked. It affects the straight muscles of the abdomen, the adductors of the thigh and the diaphragm; rupture of muscle and hæmorrhage may result. Osteo-periostitis of the tibia, vertebræ and other bones may be due to infection with the typhoid bacillus or to secondary invaders. Superficial abscesses, degenerative changes in the central nervous system or peripheral nerves, and venous thrombosis are also sequels of typhoid infection.

Symptoms and Course.—The period of *incubation* averages from 10 to 14 days, but may be as short as 5 days or as long as 3 weeks. During this period symptoms are generally absent, but ill-defined malaise or, more rarely, gastro-intestinal disturbance may occur.

The *onset* is generally insidious with chilliness, lassitude, loss of appetite and muscular pains. Symptoms which are particularly suggestive are frontal headache, oozing epistaxis, slight bronchitis and disturbing dreams. The tongue becomes furred, the mouth dry and the bowels loose or constipated. The patient may not take to bed for a day or two. The temperature mounts gradually, being a degree or more higher each succeeding night with morning remissions. By the end of the first week the patient's condition is characteristic. The aspect is heavy and the cheeks are flushed. The lips and mouth are dry, and the dorsum of the tongue covered with a dirty white fur, the tip and edges being raw. The abdomen is slightly tumid, with gurgling in the right iliac fossa. The bowels are loose, several liquid motions like pea soup being passed in the 24 hours; sometimes, however, there is constipation. The spleen may be palpable. A characteristic feature is a moderately full but easily compressible pulse, the frequency of which is not increased in proportion to the temperature. The respiration is accelerated. The temperature will by now have attained a maximum of 103° to 105° F., still showing morning remissions of about 1°, and is unstable, reacting quickly to minor disturbances. The urine is high coloured and concentrated, and the skin usually dry. Thirst and headache are the chief complaints.

The rose spots usually make their appearance towards the end of the first week, sometimes on the fifth day, more often between the seventh and twelfth. Each spot is a circular, slightly elevated papule of a pale pink colour from 2 to 4 mm. in diameter, disappearing on pressure. The rash should be sought for on the abdomen, the flanks, the sides of the chest and the back, which should always be scrutinised. The spots appear in successive crops, each one fading in 3 or 4 days, and leaving a transitory brownish stain. Often the eruption is scanty, a few spots only being seen; occasionally it is very profuse, and involves the limbs as well as the trunk. The face usually escapes. Minute sudaminal vesicles occasionally cap some of the spots. The eruptive period lasts from 10 days to 3 weeks. A profuse rash does not necessarily indicate a severe attack. The spots are due to bacterial embolisms.

By the second week the fever (Fig. 3) has reached its fastigium. The temperature maintains its level with slight morning remissions, the headache may abate, but prostration increases and the other symptoms are more severe. The lips become cracked, sordes accumulate on the teeth, the

abdomen becomes more distended and diarrhoea is often a marked feature, the stools being liquid, yellow in colour, alkaline and foul. They may be chocolate-coloured or red from admixed blood and small shreds of tissue, or actual sloughs may already be present. The evacuations are not accompanied by colic or tenesmus. The spleen is now larger. The pulse rate will have quickened to a frequency of 112 to 140. It is often dicrotic, and the heart sounds enfeebled. The bases of the lungs may now show signs of hypostatic congestion, and the respiration be more accelerated with slight lividity of the lips and face. The patient may be deaf and unresponsive. Delirium of a muttering character disturbs the sleep, asthenia is very marked and muscular wasting rapid. The urine may be albuminous and scanty. Patients may succumb during this period from toxæmia, or towards the end of the first fortnight from perforation of the bowel or intestinal hæmorrhage.

During the third week improvement should occur, the temperature becoming more remittent in type, the morning reading falling more rapidly

FIG. 3.—Typhoid Fever from the first day. Illustrating gradually rising temperature, a "continued" stage, and a typical lysis.

than that of the evening. The tongue cleans and appetite begins to return. During the fourth week defervescence may be completed, the temperature usually remaining at a subnormal level for some time. In severe infections, however, the third week is a period of increasing anxiety. The symptoms increase in severity and the patient may pass into the "typhoid state," lying on the back in a semi-stuporose condition. The pulse and heart sounds become more and more enfeebled, the pulmonary congestion increases, the extremities become blue and cold, subsultus tendinum appears, and the evacuations are passed unconsciously. Sometimes there is retention of urine. Extreme abdominal distension may supervene, and the occurrence of perforative peritonitis or of hæmorrhage from the bowel is more than ever to be dreaded. In such severe cases the fever may be prolonged through the fourth and fifth weeks before any signs of defervescence appear. They are not necessarily fatal.

Convalescence after a severe attack is always protracted. The temperature is at first subnormal, and remains in a very unstable state. The heart sounds remain enfeebled, and the pulse is often rather fast or easily quickened by exer-

tion or excitement. On the composite chart the falling temperature and rising pulse curves will cross. The effort of standing and walking is difficult and painful. The appetite, however, is good, and the weight rapidly increases. The aspect gradually becomes less anæmic. Slight peeling of the skin, loss of hair, and ridging or furrowing of the nails is often noticeable. During this period the feet and ankles may show slight œdema, and cutaneous abscesses or localised bone abscesses may occur. Femoral thrombosis sometimes appears; it is the chief complication of early convalescence.

Relapse.—Tendency to relapse is a marked feature, and shows itself in from 5 to 15 per cent. of the cases. The relapse may occur during actual defervescence, but more commonly develops after an afebrile period of a week or a little longer. The symptoms are a repetition of those of the original attack, but in a mitigated form, the fever reaching its acme in a shorter time, and the whole duration being 10 days or a fortnight. The spleen enlarges again, a new crop of rose spots usually appears, fresh ulceration of the bowel occurs, and blood culture may again prove positive. On occasions, the relapse equals or exceeds the original attack in severity, and may even prove fatal. Second and third relapses are not unknown. Spurious relapses are recrudescences of fever during convalescence, of short duration, and unaccompanied by definite symptoms. Their explanation is often obscure.

VARIETIES.—The fact that typhoid fever may show great variations in its clinical characters, and in the severity and prominence of different symptoms, has led to the description of many special types. Different epidemics may differ much in their salient features.

Variations in onset.—The onset of symptoms may be sudden, sometimes with rigors and vomiting. The temperature rises quickly, and delirium may supervene early. In such cases, death may occur during the second week, or the disease may gradually assume the ordinary type. In exceptional cases, severe bronchitis or pneumonia may mark and mask the onset, and the true nature of the infection may be overlooked. The prominence of meningeal symptoms may lead to confusion with cerebro-spinal fever, and the differential diagnosis only be possible by examination of the cerebro-spinal fluid. If typhoid meningitis is present, lymphocytes or polymorphs predominate, according to the severity of the infection, and the typhoid bacillus grows on culture. More commonly the fluid is under tension but clear; it is sterile and the meningeal symptoms quickly subside after lumbar puncture, to be succeeded by the more typical signs of typhoid fever (see also p. 1591). Yet another occasional mode of onset is with a primary acute hæmorrhagic nephritis. When acute gastro-intestinal symptoms signalise the invasion, appendicitis or irritant poisoning may be simulated.

The terms *pneumo-typhoid*, *meningo-typhoid* and *nephro-typhoid* have been used to designate some of the above-mentioned types.

Variations in course.—There is an ambulatory form in which febrile disturbance is generally slight, and the patient continues about during the whole or the greater part of the illness. Some such cases end in recovery; but others run a very severe course, the patient taking to bed about the end of the second week with aggravated symptoms, or succumbing to hæmorrhage from the bowel, perforation, acute delirium or circulatory failure. Mild and abortive forms of typhoid also occur in which the fever is insignificant, or, after a well-marked onset, ends in a rapid defervescence between the eighth

and fourteenth day. An afebrile form is known, and is said particularly to occur in the enfeebled or those exposed to great hardships.

Variations due to age, pregnancy and other causes.—Typhoid fever is rare in infancy, but becomes more frequent in childhood, and then, generally, the symptoms are mild, the pyrexia of short duration and sometimes of a markedly intermittent or remittent type. A primary bronchitis or gastro-enteritis may be simulated. Such complications as perforation or hæmorrhage are rare.

In the aged, particularly in those over sixty, typhoid tends to run an unfavourable course, hypostatic pneumonia and circulatory failure being common.

Abortion or premature delivery takes place in from 50 to 70 per cent. of pregnant women who contract typhoid. The fœtus is dead or, if born alive, usually succumbs to an acute typhoid septicæmia. The prognosis as regards the mother is not especially influenced.

In malarial patients the onset of typhoid may be sudden, with a typical rigor; but the severe symptoms proper to typhoid develop later. On the other hand, subtertian malaria may closely simulate typhoid in its commencement.

Chronic alcoholism exerts a very unfavourable influence. Pre-existing pulmonary tuberculosis is apt to advance rapidly during convalescence from the fever. In diabetes typhoid often runs a mild course.

Special Symptoms and Complications.—*Digestive system.*—Suppurative parotitis is attributed to duct infection, and occasionally leads to cellulitis. Attention to the cleansing of the mouth goes far to prevent it. Ulcers sometimes appear on the pillars of the fauces and the pharyngeal wall (Duguet's ulcerations). Diarrhœa is not a constant feature, some patients being constipated throughout the disease. The diarrhœa often disappears after a few days' hospital treatment, but in grave infections it may be severe and persistent.

Meteorism with a distended, tense, tympanitic abdomen signifies a virulent infection. It may or may not be accompanied by severe diarrhœa, and is often a harbinger of hæmorrhage or perforation.

Intestinal hæmorrhage occurs in about 7 per cent. of all cases, and is serious. It is most common at the time when the sloughs are separating, *i.e.* at the end of the second or beginning of the third week. The hæmorrhage may be slight, but more often is profuse. The evacuated blood is bright red in colour, unless it has been retained in the bowel. The signs of a severe hæmorrhage are a sharp fall in the temperature, a sensation of faintness, increased frequency of the pulse and, it may be, a transient rise in blood pressure with disappearance of dirotism. The spleen may shrink rapidly. Sometimes the hæmorrhage is fatal before any blood is voided.

There is also a hæmorrhagic form of typhoid in which melæna may be an early sign, associated with petechiæ or bruises in the skin and hæmaturia. The outlook, then, is very grave.

Perforation of the bowel causes one out of every 3 or 4 deaths. Its incidence is something under 5 per cent. It is commonest towards the end of the third week, especially in cases characterised by severe diarrhœa or by meteorism. Its onset may be preceded by intestinal hæmorrhage. The perforation generally lies within the last 12 inches of the ileum, but may

occur elsewhere. Shivering, with sharp pain in the right iliac fossa, is usually the first sign. Localised tenderness, localised rigidity and local immobility of the abdominal wall accompany the pain. The temperature may show a sudden drop to subnormal followed by a rise; but sometimes no variation is detected. Both pulse and respiration rates are usually increased, and the former should be watched carefully. Obliteration of the liver dullness may occur; this sign is especially valuable when occurring in a rigid and retracted belly. Another sign is the occasional onset of irritability of the bladder. More reliance should be based on the local than on the general symptoms in making the diagnosis. After the first shock the patient may react and show deceptive signs of improvement, but before many hours the signs of spreading peritonitis will assert themselves. Unless dealt with surgically with the utmost promptness perforation is almost invariably fatal. A polynuclear leucocytosis generally accompanies perforation, but is inconstant and not of great diagnostic value.

Other causes of abdominal pain in typhoid fever are acute cholecystitis, suppurative cholangitis, portal pyæmia, suppurating mesenteric glands, appendicitis and splenic infarction, but none of these is common. Thrombosis of the iliac veins may also cause pain and tenderness, but a clue to this condition may often be found by examining the veins of the lower limbs and by looking for slight œdema of the leg or foot.

A transient hepatitis sometimes occurs, but jaundice is rare. Gall-stones are a recognised sequel of typhoid infection and may contain the bacilli.

Respiratory system.—A mild bronchitis is present in most cases. In severe infections, hypostatic congestion of the lung bases occurs. Lobar pneumonia may supervene in the third or fourth weeks of the disease. Although typhoid bacilli may occur in the sputum, and be found in the lung, pneumococci are also present; the condition may be overlooked, as cough is often slight and rusty sputa absent. Embolic and pyæmic processes in the lungs during typhoid may give rise to abscess, gangrene and pneumothorax. Intra-pulmonary thrombosis, with infarction, is a very rare event.

Ulceration of the larynx is not infrequent in severe cases. It involves the post-arytænoid region and has been likened to a pressure sore. It may be latent or give rise to huskiness of the voice, stridor and toneless cough. There may be pain on deglutition and laryngeal tenderness. The slighter symptoms may abate, but sometimes the process terminates in necrosis of cartilage and œdema or stenosis of the larynx.

Blood and circulatory system.—A slight polynuclear leucocytosis is sometimes seen in the first week of infection. More characteristic is anæmia associated with leucopenia, a characteristic absence of eosinophils with a relative increase in the lymphocytes and large mononuclear cells. In uncomplicated typhoid fever the leucocyte count rarely exceeds 6000. The eosinophils reappear with convalescence. The appearance of a polynuclear leucocytosis indicates the onset of inflammatory complications.

Circulatory failure is a feature of severe attacks. The pulse rate, usually but moderately accelerated in typhoid, rises to 120 or more, dicrotism disappears, the cardiac sounds weaken, and the blood pressure falls. Acute collapse, with sudden drop of temperature, coldness of the skin, cyanosis and feeble or irregular pulse, may ensue. The collapse may be recovered from, but its occurrence is ominous.

Femoral thrombosis is apt to appear during early convalescence. It is usually left-sided, and sometimes appears to commence lower down in the veins of the popliteal space or calf or in the internal saphenous trunk. The symptoms are pain and tenderness at the site of the thrombosis, fever and swelling of the limb, usually moderate in degree. The affected vein may often be felt as a tender cord. In a few weeks the thrombus is absorbed, and the circulation re-established, but sometimes permanent obstruction and cedema result. The clot, if dislodged, may cause pulmonary embolism.

Arteritis, leading to occlusion, is an uncommon complication. The vessels affected are those of the lower limbs, sometimes those of the upper extremities, neck or brain.

Urinary system.—Febrile albuminuria is often present, but is transitory. Typhoid bacilluria occurs in some cases, the urine presenting a slightly turbid, opalescent appearance; but a similar appearance may be due to the colon bacillus. Symptoms of pyelitis, pyelo-nephritis or cystitis may supervene. Urinary carriers continue to discharge typhoid bacilli for long periods. Acute nephritis is uncommon, but may occur either at the commencement or height of the disease. Retention of the urine may supervene during typhoid, but suppression is rare. During the fever the excretion of urea and of uric acid is increased, but the chlorides are diminished. A moderate oliguria is the rule. A considerable reduction, in spite of free fluid intake, is evidence of a severe attack. Polyuria occurs at the onset of convalescence, and is of good omen.

Generative system.—Orchitis and prostatitis have been observed. In females vulvitis and also mastitis may occur.

Nervous system.—Meningeal symptoms at the onset have already been mentioned (p. 85). Rarely meningitis occurs in a purulent form during the third or fourth week of the disease. Its mortality is high (50 to 100 per cent.). Delirium is often present and is usually of a quiet type. Drinkers may develop delirium tremens. Convulsions are rare. They may occur at the onset, or when occurring later may be due to cerebral thrombosis, encephalitis, or meningitis. Multiple neuritis or neuritis of such nerves as the ulnar or peroneal may supervene, in the latter cases often due to pressure. Acute tenderness of the toes during convalescence is also attributed to neuritis. During the course of the fever hemiplegia or aphasia may supervene. Sometimes there are signs of sclerosis of the lateral columns of the cord, the knee-jerks being increased, and an extensor plantar reflex present.

Mental disturbance is occasionally a sequel, taking the form of mania, melancholia or dementia. For many months after a severe attack the patient may remain in a fatuous condition but ultimately recover.

As regards the special senses, temporary deafness is often noticeable during the fever, and sometimes suppurative otitis. Double optic neuritis is a rare complication which may lead to blindness.

Oseous and muscular systems.—During convalescence localised osteo-periostitis of the tibia, sometimes of the femur, ribs or other bones may appear. It may terminate in suppuration with limited necrosis. The inflammation is chronic and relapsing. Typhoid bacilli may persist in the pus for long periods. A painful inflammatory affection of the ligaments and vertebral periosteum is the basis of the "typhoid spine." The lumbar and sacral regions are chiefly involved, with stiffness and pain on movement. The

condition is chronic, but the ultimate outlook is said to be good. Arthritis of large joints is a rare occurrence; it may lead to dislocation of the hip.

Rupture of the rectus abdominis, sometimes of the adductors or other muscles, may take place. It is accompanied by local hæmorrhage. The resulting fluctuating and discoloured swelling may clear up or go on to suppuration.

Cutaneous system.—Abscesses and boils may prove troublesome. Lineæ atrophicæ tend to form in the skin of the abdomen and thighs. In severe cases pressure sores may appear on the sacrum, the heels or other pressure points. These bed-sores are a source of danger from septicæmia or pyæmia.

Diagnosis.—It is unnecessary to recapitulate all the symptoms already described as characteristic. Of the symptoms of onset, headache, slight epistaxis, disturbed sleep, a mild degree of bronchitis, abdominal uneasiness and some disturbance of the action of the bowels are very suggestive. Gradual daily increase in the pyrexia and its maintenance after the lapse of a week at a steady level of 103° or 104° F., with slight morning remissions, is important. Relative slowness of the pulse and the presence of dicrotism are additional diagnostic points. The dry furred tongue peeling in lateral and central strips, slightly tumid abdomen, moderately enlarged spleen and the appearance of rose spots are confirmatory. The abdominal reflexes are often absent.

SPECIAL DIAGNOSTIC METHODS.—1. *Blood examination.*—Culture is particularly valuable in the first week before the agglutinative reaction has appeared or the rose spots are evident, but is also applicable during the second and third weeks and in relapse. Ten to 20 c.c. of blood drawn aseptically from a vein at the bend of the elbow are allowed to run directly into plenty of broth or peptone solution or, better, into a medium which contains filtered bile or bile salts. At the same time a blood count should show a characteristic leucopenia with a relative lymphocytosis.

2. *Cultures from bone-marrow* obtained by sternal puncture are said to be more often and more persistently positive than blood cultures.

3. *Cultures from the stools.*—Owing to the presence of other intestinal bacteria this is not always an easy process, but by enrichment methods and the use of litmus-lactose agar, or MacConkey's medium or the bismuth sulphate medium of Wilson and Blair, bacilli have occasionally been found during the incubation stage and in over 50 per cent. of the cases examined in the first week, a percentage increased to 70 or 80 in the third week. Stool culture is also of value for the detection of intestinal carriers, and for determining whether a convalescent is fit to mix with other members of the community. The discharge of bacilli often being intermittent, more than one examination is necessary.

4. *Cultures from the urine.*—The typhoid bacillus hardly ever appears in the urine before the tenth day, and as a rule not before the fifteenth. The infected urine is generally opalescent and slightly albuminous. Cultures are made without difficulty and are useful not only for diagnosis but also for the detection of urinary carriers.

5. *Agglutination tests.*—Towards the end of the first week of typhoid fever the blood serum becomes capable of agglutinating the typhoid bacillus. This power reaches its maximum about the eighteenth to the twenty-third day. The test is performed with standardised suspensions and repeated every 4 or 5 days. An agglutination titre of 1 : 100 is regarded as positive. Normal

blood rarely shows an agglutination higher than 1 : 50. Rising titres are highly diagnostic. Dreyer standard suspensions, being formolised, produce H or flagellar agglutination only. This is specific in the case of *B. typhosus* and *B. Paratyphosus A*. *B. Paratyphosus B*, however, may occur either in the specific or in the group phase, and in the later case possesses agglutinative elements which are common to other members of the *Salmonella* Group and so its antiserum may agglutinate these organisms.

A second agglutinin, known as O or somatic, should be investigated at the same time. The actual titres obtained with this usually are less than those obtained with H. An O agglutination is also possible with other members of the *Salmonella* Group, and O agglutination is not so specific as H.

A third agglutinin, known as the Virulence or Vi antigen, appears early and is usually transitory. It affords strong evidence of recent infection. In chronic typhoid carriers it persists and is said to be of value in their detection.

As a continued fever of the enteric type may, although rarely, be caused by other members of the *Salmonella* Group, it is now customary to employ a formolised suspension of B para B, H specific, and also of B. para B or some other member of the family in the group phase.

T.A.B. vaccine, in consequence of its mode of preparation, evokes H agglutinins chiefly, and these may persist for some years. The appearance of O agglutinins in an inoculated person shows an enteric infection. Blood culture or examination of the excreta may reveal its identity. A rising titre of H agglutination for a particular organism may also do this, but it is known that other, quite different, infections may also raise the H titre (*anamnesic reaction*).

6. *The atropine test of Marris*.—In typhoid and paratyphoid fevers atropine has but little power of accelerating the pulse. Marris's test is based on this fact, but is little used.

7. *The Diazo reaction*.—A saturated solution of sulphanilic acid in 1 in 20 hydrochloric acid and a fresh half per cent. solution of sodium nitrite are required. Equal quantities of urine and sulphanilic solution are mixed in a test-tube and a couple of drops of the nitrite added. By shaking, a froth is induced and ammonia is allowed to trickle down the side of the tube. If the froth becomes rose pink and the liquid turns crimson, the test is positive. The reaction may sometimes be obtained as early as the fourth day, and persists during the height of the fever. The fact that it also occurs in measles, typhus fever, scarlet fever, pneumonia, tuberculosis, erysipelas, and after administration of sulphapyridine detracts from its value.

DIFFERENTIAL DIAGNOSIS.—Prominence of respiratory or bowel symptoms in typhoid fever may lead to the infection being overlooked. A deep-seated or apical *pneumonia* or, in children, *broncho-pneumonia* with intestinal disturbance, may simulate typhoid. Careful and repeated physical examination, blood and stool culture and agglutinative reactions will lead to a correct diagnosis. Labial herpes is rare in typhoid. When typhoid is prevalent, caution is necessary in diagnosing primary bronchitis, pneumonia, broncho-pneumonia, and, especially in children, gastro-enteritis.

Differentiation from *acute miliary tuberculosis*, from *tuberculous meningitis* and from *tuberculous peritonitis* is often difficult. Acute miliary tuberculosis may simulate typhoid in its insidious onset with malaise and headache, its rising temperature with morning remissions, its occasional slow

pulse, its bronchitis, and perhaps some enlargement of the spleen. But the temperature tends to be more irregular, sweats are present, the dyspnoea and cyanosis are suggestive, and signs of pleurisy may develop. There are no rose spots, and agglutinative tests and blood culture give negative results (tubercle bacilli are rarely found). Tuberculous meningitis is differentiated by such symptoms as vomiting, convulsions, the persistence of headache after the first week, or when delirium is established. A pulse hardly raised above the normal rate, stiffness and retraction of the neck, the presence of Kernig's sign and of retraction of the abdomen or the onset of ocular paralysis are very significant. The irritability and curled-up decubitus of meningitis contrasts with the apathy and dorsal decubitus of typhoid. Lumbar puncture will clinch the diagnosis; in tuberculous meningitis lymphocytes are in excess in the cerebro-spinal fluid, and sometimes tubercle bacilli may be demonstrated. The question of meningo-typhoid has already been discussed. Tuberculous peritonitis may resemble mild typhoid fever. The presence of tuberculous masses in the abdomen or the development of peritoneal or pleural effusions is significant. In cases with indefinite symptoms and no signs of tubercle elsewhere, negative blood culture and agglutination tests afford assistance in eliminating typhoid infection.

Suppurative and pyæmic conditions may give rise to fever and constitutional disturbance bearing some resemblance to typhoid. Among these must be mentioned appendicitis and the intraperitoneal abscesses which may result from it, perinephric abscess, cholecystitis, pelvic, or puerperal infections, infective endocarditis and deep-seated osteomyelitis. The diagnosis is made by careful attention to the history of onset and course, thorough and complete physical examination, and the frequent presence of a pronounced polynuclear leucocytosis. Profuse sweats and rigors are more likely to occur, and the temperature chart is more irregular. The blood serum fails to agglutinate typhoid bacilli, nor can they be obtained by blood culture, which may, however, reveal the presence of other organisms.

Typhoid fever in its early stages is often mistaken for *influenza*, but in the latter the onset is generally sudden and the early symptoms are more severe. The temperature reaches its maximum much sooner. The pains in the limbs and the backache are more intense, and the headache, which has a neuralgic character, is frequently supra-orbital. Catarrh of the conjunctivæ and nose may be present, and perspirations are often marked. Defervescence usually takes place within a few days. A sharp drop of temperature after 2 or 3 days with a sudden rebound 12 or 24 hours later is very characteristic. If a supposed influenzal fever persists without definite cause, typhoid should be suspected.

A mild case of *typhus* may bear a close resemblance to typhoid, and severe typhoid with grave toxæmia, stupor and a profuse eruption may be mistaken for typhus. Points in favour of the disease being typhoid are a slower onset, later appearance of the eruption, which is never petechial, and presence of bowel symptoms. Typhus, on the other hand, has a sudden onset with high fever which sooner attains its maximum and does not show morning remissions. Conjunctival injection, contracted pupils and a drunken expression are the rule. The rash appears on the fourth day, becomes petechial and is accompanied by subcuticular mottling. Prostration is marked and there is a greater tendency to early delirium or stupor.

Defervescence, more or less abrupt, occurs about the fourteenth day. The Weil-Felix reaction is present, but agglutination tests for typhoid are negative except in inoculated persons (p. 306).

Undulant (Malta or Mediterranean) fever is distinguished from typhoid by its persistently relapsing character, the prominence of arthritic pains and joint swellings, and the fact that the blood agglutinates the *Micrococcus melitensis*, which organism can also be recovered by blood culture. Closely allied to this is the fever produced by *B. abortus* of cows.

When *malarial fever* assumes the continuous type, which is likely to occur with the malignant infections, the diagnosis turns on known exposure to malaria, sudden onset, the detection of malarial parasites in the blood or bone marrow and the reaction to quinine. Malaria and typhoid fever, however, may coexist.

The fever of *secondary syphilis* is sometimes sufficiently severe to suggest typhoid, especially when accompanied by headache, malaise and muscular pains. Diagnosis depends on the history or detection of a primary lesion, the possible presence of a secondary roseolar eruption and on laboratory tests. Deep-seated *malignant disease* hypernephroma may also cause prolonged fever.

Amongst other diseases at times confounded with typhoid must be mentioned psittacosis, kala-azar, glanders, trichinosis, fever due to *Ascaris lumbricoides*, scarlet fever in which pyrexia is prolonged, that type of glandular fever in which the glandular swelling is delayed, and especially fevers of the Salmonella group, i.e. paratyphoid A, B or C.

Prognosis.—Taking all ages, the death-rate varies from 5 to 25 per cent. as is higher in some epidemics than in others. The average hospital death-rate in London is 17 per cent. or a little less. Age has a decided influence especially on the mortality, which is least in children from 5 to 10, after which there is a steady increase with advancing years. Infants are believed to stand the infection very badly. Obesity, alcoholism, privation and fatigue are adverse factors. The influence of pregnancy has already been discussed. Indications of a grave attack are a pulse rate of 130 or 140, cyanosis with signs of failing circulation and hypostatic congestion of the lungs, marked delirium and subsultus or actual coma, oliguria, persistent diarrhoea, tympanites, incontinence of urine and faeces. A temperature of 103° or 104° F. is not necessarily unfavourable unless it is sustained beyond the usual period or accompanied by signs of heart failure. Delayed appearance of the agglutination reaction in some instances indicates a severe attack.

Of the complications, next to toxæmic circulatory failure, perforation is the most grave. Without operation it is almost invariably fatal. With operation the recovery rate is difficult to fix—some surgeons claim success in over 30 per cent., but the intervention must be immediate. The average recovery rate is very much lower. Hæmorrhage from the bowel is undoubtedly serious, especially if repeated. Such complications as meteorism, meningitis, lobar pneumonia and acute nephritis are dangerous but not very common.

Sudden death sometimes occurs, either at the height of the fever or in convalescence. It may be caused by intense toxæmia and circulatory failure, cardiac or pulmonary thrombosis or pulmonary embolism. Rarely no definite cause can be assigned.

Treatment.—**PROPHYLACTIC.**—Patients should be isolated. Adequate

disinfection of the faeces, the urine, the pus from abscesses, the vomit and the sputa is necessary. Blood discharged from the nose or bowel should also be looked upon as infectious. Equally essential is the disinfection of the bedclothes and personal linen of the patient, the feeding utensils, thermometer, bed-pan, urinal, spittoon and enema syringe. The stools and urine should be mixed with an excess of some such disinfectant as carbolic acid or corrosive sublimate, and allowed to stand for several hours before being thrown down a drain. The sputa should be received in small cloths which can be burned, or expectorated into a disinfectant solution. The clothing and bedclothes of the patient should be soaked in a 1 in 20 solution of carbolic acid before being sent to a laundry.

Nurses in attendance should submit to prophylactic inoculation and take special precautions for their own safety. Overalls will obviate soiling of the clothes. If the bath treatment is adopted, rubber aprons which can be carbolised are advisable. Rubber gloves may be worn when giving enemas or touching bed-pans and urinals, but always it should be realised that typhoid acquired by contact is a disease conveyed by unclean hands, and the danger may be obviated by washing with plenty of soap and water after touching the patient or anything which has been in contact with him. Everything leaving the patient or used by him must be sterilised at once. Feeding utensils should be boiled after use.

In most cases the bacilli disappear from the excreta in convalescence, only persisting for a few weeks, but bacteriological examination several times repeated affords the only proof of safety. About 5 per cent. of those attacked become carriers. In most the carrier state is temporary and an arbitrary period of 6 or 12 months is allowed before the condition is deemed chronic. Intestinal carriers are more common than urinary carriers. In both the discharge of bacilli may be intermittent. Symptoms referable to the gall-bladder and periodic bowel disturbance occur in some intestinal carriers, and urinary carriers in like manner may suffer from kidney trouble or cystitis. Female carriers are said to be more common than male. Carriers do not necessarily give a positive Widal reaction, but Felix states that use of the Vi antigen will detect them (see p. 90).

Carriers are often responsible for the endemic persistence of typhoid in certain houses or localities and are particularly dangerous when employed in the preparation of food or in dairy work or in connection with water supplies. They should be prohibited from following these occupations. Since they may spread infection by contaminating their own hands during defaecation or micturition they should be scrupulous in washing after attending to the calls of nature and have towels reserved for their own use. Their soiled bed and body linen must be disinfected. Medical treatment by the use of intestinal and urinary antiseptics, surgical by excision of the gall-bladder, and treatment by autogenous vaccines have up to now alike failed to solve the problem of the chronic carrier. It is said that sulphaguanidine is sometimes effective. Preventive inoculation of contacts is the most effectual method of limiting their danger and is adopted in special circumstances. Some carriers give no history of an attack of typhoid and may themselves ultimately develop an attack of the fever or suffer from typhoid septicaemia after operations on the gall-bladder or kidney.

A pure water supply and an efficient system of drainage are important

factors in the prevention of typhoid epidemics. When the disease is prevalent, drinking water and milk should always be boiled, and travellers in localities where it is endemic should adopt similar precautions. Uncooked vegetables and, in particular, radishes, salads, cress, tomatoes, cucumbers, strawberries and other fruits are liable to contamination. Oysters and other shell-fish should be avoided unless their source is known to be above suspicion. The disease has been contracted by bathing in sewage-contaminated water.

Prophylactic vaccination.—Immunity can be artificially induced by vaccination with typhoid vaccine. There are several methods of preparation of vaccine, one of which is to heat a 48-hour broth culture to 58° C., and complete the sterilisation by the addition of 0.5 per cent. lysol. Exposure to higher temperatures diminishes the potency of the vaccine. The number of bacteria in the first dose is 500 million, a double dose is given 10 days later and repeated 10 days later still. Felix advocates an alcohol killed and alcohol preserved vaccine made from smooth cultures virulent to mice. This stimulates formation of Vi and O agglutinin and has proved highly effective. Vaccine injection is made subcutaneously and preferably not after a heavy meal or exposure to fatigue. A mild local reaction and sometimes constitutional symptoms may occur a few hours after injection, hence the patient should rest. If the patient is already infected the reaction may be more severe. The duration of the immunity conferred is said to average 1 to 2 years and to be proportional to the dosage employed. An individual inoculated at the beginning of the incubation period of typhoid has a good chance of escaping the fever, but in rare cases the inoculation appears to precipitate its onset and aggravate its course (*provocation typhoid*). For army purposes, triple or quadruple vaccines of the organisms of typhoid and paratyphoid are largely employed.

CURATIVE.—In the absence of efficient drugs, sera or vaccines there is at present no specific. Skilful nursing and suitable diet are of the first importance. The room should be kept at a temperature of 60° F., the bed narrow and of convenient height. A hair or rubber mattress is covered with two folds of blanket and a waterproof sheet over which is placed a sheet, and under the hips a draw sheet. A water-bed is unnecessary. A sheet and coverlet with a blanket over the feet are usually sufficient covering. Night and morning the patient should be sponged with tepid water, and parts exposed to pressure should be rubbed with surgical spirit, and dusting-powder applied. Rucking of bedclothes should be avoided. The urinal and bed-pan should be used in the recumbent position, and the buttocks sponged, dried and powdered after each motion. The mouth should be cleansed after each meal. From time to time it may be advisable to move the patient from the dorsal position to avoid hypostatic congestion of the lung bases. Stools and urine should always be reserved for inspection by the medical attendant, who should never neglect daily examination of the abdomen, and should also satisfy himself that the patient, especially if restless, has not retention of urine. The temperature pulse and respirations should be charted 4-hourly, and more frequently should complications be suspected.

Milk is the most suitable diet for patients in the acute stages. It should be given in measured quantities at 2- or 3-hourly intervals, the patient not

being disturbed at night should he be sleeping. Three pints a day is, despite theoretical considerations, quite sufficient. The milk should be diluted with barley water or lime water, and plenty of plain cold water or fruit juice given between the feeds. Tea may be allowed or lemonade made with dilute hydrochloric acid and syrup of lemons. Should intestinal discomfort occur or curds appear in the motions the milk may be citrated or whey substituted. Beef-tea and meat extracts are to be avoided in diarrhoea or hæmorrhage. Carbohydrate can be added to the diet in the form of glucose or lactose. Junket, ice-cream and also apple-sauce are useful adjuncts.

When the temperature has been normal for 3 days, cautious additions may be made, beginning with thin custard or grated bread-crumbs and milk, and then adding a small quantity of boiled or steamed fish, thin bread and butter, and so on.

High calorie diets are based on the belief that during the fever a daily intake of 4000 to 5000 calories is necessary to maintain nitrogenous equilibrium. Even in patients who are amenable this diet is prone to produce digestive upsets and meteorism, but mild cases can take a more liberal diet during the acute stage, *i.e.* milk puddings, custards, eggs, vegetable or meat soups strained and thickened with arrowroot or flour, finely minced lean meat, bread crumbs and mashed potato. Such feeding is said actually to diminish the tendency to perforation and hæmorrhage, and to hasten convalescence. It is not suitable in severe attacks or for patients with profound toxæmia and deficient digestive secretions. Alcohol is rarely necessary, but it is unwise suddenly to deprive alcoholic patients of all stimulants.

In an infection of moderate severity the patient should be able to be out of bed for a short period 10 days after the temperature has become normal.

The antipyretic treatment of typhoid assumes that pyrexia itself is harmful. The cold bath is most efficient. Best suited to hot climates, it has never gained a great vogue in England. Whenever the temperature rises above $102^{\circ}\cdot3$ F., the patient is lifted into a bath at 65° F. and immersed for 15 minutes, shivering being disregarded. The limbs and trunk are rubbed whilst in the bath. The patient is then removed, laid on a blanket, dried and lightly covered. A little alcohol is given immediately before or after the bath. Immersion is repeated every 3 hours unless the temperature remains below the point mentioned. Contra-indications are hæmorrhage from the bowel, severe abdominal pain, venous thrombosis or great prostration. The method needs good attendants, and can hardly be applied in private, but it is said to reduce the case mortality by a half or even two-thirds. In place of the bath, tepid, cold or ice sponging may be adopted when the temperature is high, or the cold pack used, especially when nervous symptoms are pronounced. The ice cradle is another useful means of refrigeration; the patient is covered with a sheet, and a cradle, in which small rubber bags of ice are suspended, is placed over the body, the whole being covered with a thin blanket. The cradle may remain in position indefinitely, the effect on the temperature being carefully watched.

Some advocate daily mild purges, such as calomel or drachm doses of castor oil, in the early days of infection, and claim that intestinal fermentation can be checked by the administration of various intestinal antiseptics.

Constipation should be met by a simple enema every second day. In defervescence liquid paraffin may be substituted. *Diarrhoea*, if accompanied

by curds, calls for reduction of the milk. A starch and opium enema is useful, or 10 grains of Dover's powder by the mouth. In *hæmorrhage from the bowel* the most absolute rest is essential. Food should be reduced to a minimum or withheld for 12 or 24 hours. No stimulants or beef-tea are permissible. Ten minims of laudanum or a hypodermic injection of $\frac{1}{4}$ grain of morphine should be given, and an ice-bag applied to the right iliac region. A watch should be kept for signs of perforation. Intravenous saline infusion, or, better, transfusion of blood, may be necessary in severe cases. The injection of a solution containing 1 grain of calcium chloride in 10 minims of water into the gluteal region is worth a trial. *Perforation of the bowel* calls for immediate operation. *Meteorism* may be controlled by reducing the diet, administering copious enemata of hot water, and inserting the rectal tube. A turpentine stupe or ice-poultice may be applied to the abdomen. Turpentine by the mouth or by enema, and oil of cinnamon are useful. For *delirium*, *sleeplessness* and *headache*, the reduction of temperature by sponging or cradling and the administration of 10 or 15 grains of Dover's powder should be tried. Sometimes soluble barbitone (medinal) and aspirin are effectual. *Circulatory failure* is combated by strychnine or strychnine and adrenaline hypodermically, or by injection of nikethamide (coramine) or leptazol (cardiazol). Strophanthus and digitalis are of doubtful value. Alcohol is strongly advocated by some physicians. The supervision of *femoral thrombosis* calls for strict immobility of the limb. The intravenous injection of 5 or 10 ounces of a sterile 0.5 per cent. sodium citrate solution relieves the pain, and is said to arrest the progress of the thrombosis. *Bacilluria* and *cystitis* are treated by hexamine in 10-grain doses, 3 or 4 times a day; if persistent, sulphonamides may be effective. Of the suppurative and septic complications, *periostitis* may be influenced by rest, local applications and typhoid vaccine, but suppuration calls for surgical intervention. *Parotitis* usually comes to incision. *Cholecystitis* may subside, and should be given a chance to do so, but if it persists operation becomes necessary. Crops of *boils* call for local treatment, and the appropriate vaccine, toxoid, or sulphonamide should the organism be identified. The intramuscular injection of colloidal manganese is useful in such conditions. The infectivity of purulent discharges should be remembered. Three negative stool cultures at intervals of 7 days should be obtained before discharge.

PARATYPHOID FEVER

Ætiology.—Paratyphoid fevers, like typhoid, are ubiquitous, but the type differs in different countries and different climates. The infecting organisms belong to the group *Salmonella typhi*. Paratyphoid A is prevalent in India and other tropical countries; it may possibly be endemic in the Mediterranean and parts of Western Europe, but in European countries Paratyphoid B is much more common. Of the Paratyphoid C type several varieties are known. *Salmonella kanzendorfii* is the organism usually found in Great Britain. The American type is *S. cholerae suis*, and the Balkan and Eastern type is *S. hirschfeldii*. Paths of infection in the body and the lesions produced resemble those of typhoid fever, but ulceration of the bowel is more superficial, hæmorrhage being slight and perforation rare. The infection may even take the form of a septicæmia without bowel lesions. In other cases

there is a diffuse dysenteric inflammation and ulcers are found in the colon only. The bacilli leave the body by the same channels as in typhoid.

The greatest incidence of paratyphoid infections is in the summer, earlier in the year than that of typhoid fever. All ages and both sexes are susceptible. The primary source is a patient suffering from an attack, often in an ambulatory form, less commonly a chronic carrier. The contagion may be direct or through food, drinking water or fomites. Foods not safeguarded by cooking after purchase are common vehicles of infection. Amongst these are bread; cream, synthetic or natural; ice-cream; cream pastries; cooked beef, ham and some shell-fish. Extensive water-borne outbreaks are rare, but the organisms may flourish in sewage or sewage-effluents for 3 weeks. Milk infection is usually through the agency of infected water or of a carrier. The incubation period varies from 10 to 12 days. Extremes of 4 to 24 days are known. Precocious carriers have been known to harbour the bacilli for as long as a month before developing the disease.

Symptoms.—The clinical manifestations of paratyphoid are similar to those of typhoid fever, but are generally of a milder character with a speedier ingravescence and a shorter course. Ambulatory, or almost symptomless, attacks are common, and during outbreaks the number of transitory carriers is much in excess of the cases of overt infection. On occasions, however, paratyphoid may show a severity equal to that of true typhoid. Simulation of attacks of acute irritant food-poisoning is also alleged, but these are more likely to be due to *B. aertrycke* (*B. typhi-murium*) or to mixed infections. The septicæmic stage of paratyphoid is short, rarely lasting more than a week and blood cultures for diagnostic purposes should be taken as early as possible. They are said to prove positive in 90 per cent. of the cases.

The onset is more often insidious than sudden, the invasive symptoms resembling those of typhoid, but a sudden onset is believed to be more common than in the latter disease. Shivering and vomiting are not infrequent symptoms of such invasion. Sometimes gastro-intestinal symptoms are for a time very prominent, and are particularly misleading in childhood. As with typhoid; influenza, appendicitis, meningitis, or pneumonia may at first be simulated.

The fever attains its maximum sooner than in typhoid, and may be at its height by the third or fourth day, by which time, if not before, the patient will have taken to bed. The head aches, also the back and limbs and sometimes the joints. The patient is apathetic, and the spleen is generally palpable, firm and sometimes tender. The liver may be slightly enlarged, and the gall-bladder tender if cholecystitis is present. The abdomen is generally somewhat tumid, but marked distension is uncommon. Diarrhoea may occur at the onset, but constipation is more common. Sweating is often more pronounced than in typhoid. Rose spots are present in unusual profusion in some cases. They usually appear towards the end of the first week. In size, too, they often appear larger than those seen in ordinary typhoid infection, and the rash may continue to come out after the temperature has fallen. Pulmonary complications are mild, but bronchitis and broncho-pneumonia may occur. In the more severe cases, circulatory failure may be evident. After the first week the toxæmia rapidly diminishes and it is exceptional for the patient to pass into the "typhoid state." The fever has a shorter duration and is more often remittent than in typhoid.

Within a fortnight, sometimes sooner, it has generally fallen by rapid lysis to normal. The slow pulse and low blood pressure of typhoid are also seen in the paratyphoid variety, and the blood picture, in minor degree, also resembles that of typhoid fever. Relapse is said to be just as frequent. Convalescence is rapid.

Complications.—In some cases bronchitis, or broncho-pneumonia, are prominent and may mask the real nature of the infection. Intestinal hæmorrhage is much less common and less severe than in true typhoid. Perforation is rare. Thrombosis of the femoral or saphenous veins or their radicles is not uncommon, and pleural effusions may occur. Cholecystitis and catarrhal jaundice may be due to paratyphoid organisms, as also bacilluria, cystitis, pyelitis and even pyelonephritis. Orchitis is an occasional complication, and is believed to spread from the urinary tract. Other complications, which have mostly been observed in army practice, are laryngeal ulceration, parotitis, periostitis, sometimes suppurative, peritonitis without perforation of the bowel, and pylephlebitis, attributed to lesions of the appendix.

Diagnosis.—For the differentiation of paratyphoid from typhoid and of the varieties of paratyphoid from each other, recourse must be had to bacteriological methods, *i.e.* to blood culture, agglutinative reactions and cultures from the stools and from the urine. Of these methods, blood culture in the early stages is the most satisfactory. If agglutination occurs in high dilutions with one of the paratyphoid organisms and little or not at all with the others and with the organism of typhoid, the nature of the infection is evident; but in other cases the examination has to be repeated at short intervals and the results compared. A rising agglutination for one organism indicates it as the casual agent. The possibility of confusion with *B. aertrycke* and of anamnestie reactions should be borne in mind.

Prognosis.—The prognosis in paratyphoid infections is better than in those due to the *B. typhosus*, the proportion of severe infections being much smaller, and the mortality much lower. The fatality in recent epidemics has ranged from 1 to 3·5 per cent. The causes of death are chiefly hæmorrhage, perforation, lung inflammations and toxæmia.

As regards differential diagnosis, prophylaxis and treatment, what has already been said with regard to typhoid applies. Sulphonamides are of very doubtful utility and may even prove harmful as leucopenia already exists.

DIPHTHERIA

Definitions.—A disease caused by the Klebs-Loeffler bacillus (*Corynebacterium diphtheriæ*), characterised by a membranous exudate at the site of infection and distinctive sequels of toxæmic origin, the chief being circulatory failure, paralysis, and albuminuria.

Ætiology.—Diphtheria is commonest in temperate climes. Human carriers are the cause of its endemic prevalence; local conditions being merely contributory. In its seasonal prevalence diphtheria resembles typhoid and scarlet fever, the maximum incidence being in the autumn and late winter months. An epidemic tendency is noticeable in years of deficient rainfall. Formerly a disease of rural districts, diphtheria is now endemic in cities and shows a tendency to local epidemic outbursts. Its heaviest incidence is on children between the ages of 2 and 5 years, at which age period it is

the second most fatal disease of childhood, taking first place in the second decade. New-born infants are rarely attacked. Many cases occur in adults, and rather more females than males are affected.

Catarrhal conditions of the throat predispose to the infection; convalescents from measles and scarlet fever, and in less degree those recovering from whooping-cough and influenza, are liable to contract the disease, which in the case of recent measles or scarlet fever may assume a particularly severe form. A progressive increase in infectivity and severity is often noticed during epidemics. The immunity afforded by diphtheria is short-lived. Relapses are rare. Second attacks may occur.

The disease is highly contagious, and infection is by direct or indirect contact. It is seldom air-borne even over a short distance. The organisms reside in the secretions from the nose and throat, in detached shreds of false membrane, and at times in discharges from the ears, the vulva, sore fingers, infected wounds or skin lesions.

Direct infection may result from kissing, or the reception of droplets of fluid ejected by speaking, coughing or sneezing. Indirect infection may be caused by eating or drinking utensils, handkerchiefs, towels, throat spatulas, clinical thermometers, toy trumpets, slate pencils and the like. The diphtheria bacillus readily grows in milk and produces no suspicious changes; milk thus may serve as a vehicle for spread of the disease. There is no evidence that it is conveyed by drinking water. The diphtheria of birds, cats and most other animals has not proved communicable to man and is due to a different organism, but virulent diphtheria bacilli have been found in nasal discharges and open sores of horses.

Diphtheria bacilli retain their virulence for long periods if protected from sunlight and from currents of air; hence the possibility of transmission by fomites. Sterilisation by boiling water or in the steam chamber is quite effectual.

Carriers.—Convalescents may harbour virulent bacilli in their throats, as also may others who have been in contact with the infection. Most are free from bacilli 4 or 8 weeks after the commencement of the disease, but in some the carrier state becomes chronic. The dangerous chronic carrier is usually an immune person, as shown by a negative Schick reaction. The presence of bacilli in the throat secretions of carriers is apt to be intermittent. All carriers are not equally effective distributors of the disease; intimate contact and addiction to such habits as kissing, sneezing, spitting and pencil-sucking are important in this respect. The nasal carrier is believed to be an especial source of danger. Among school children 80 per cent. of the carriers are between 5 and 8 years of age, and male carriers are two or three times more common than female. Throat and nose operations on carriers may be followed by clinical diphtheria. In the search for carriers, pallor, unhealthy tonsils, and nasal discharge are important indications, as also a history of recent sore throat. Skin carriers are the subjects of eczematous or impetiginous lesions or whitlows. The discovery of bacilli which morphologically resemble diphtheria bacilli does not necessarily prove they are virulent. Bacilli recovered from the throat are rarely harmless, but those recovered from the anterior nares, from discharging ears and from the skin often prove to be non-virulent when tested on guinea-pigs.

The Klebs-Loeffler bacillus is a non-motile, Gram-positive, non-sporing

organism which grows as a diplo-bacillus and shows a great tendency to become segmented or clubbed. The bacilli are slender rods, straight or slightly curved, and of varying length and thickness. In films they often show a characteristic grouping which recalls the letters of the Chinese alphabet. Both long and short forms occur, the length varying from 2 to 6 μ . The segmented appearance of the protoplasm is relied upon for morphological identification. A rapid diagnosis may be made from smears prepared direct from the throat, but it should be confirmed by examination of a film made from a young (6 to 18 hours) culture on blood serum or Loeffler's medium. Diphtheria bacilli ferment glucose with formation of acid, but fail to ferment saccharose. The true bacilli have been divided into *gravis*, *intermediate* and *mitis* varieties, according to their virulence. Differences in growth on a special blood-tellurite medium, coupled with starch-fermenting power in the *gravis* type and a hæmolytic tendency in the *mitis* variety, are the chief distinctive features. The clinical condition does not always correspond with these names.

Pseudo-diphtheria bacilli, which, although identical in appearance with diphtheria bacilli, are non-virulent, are frequently found in the nose and ear, more rarely in the throat. Another non-virulent organism of the same group is Hofmann's. This appears in smears as a diplo-bacillus, the elements of which are short, squat and wedge-shaped with apposed bases. It stains uniformly throughout, and is shorter than even the shortest varieties of the diphtheria bacillus. These distinctions apply only to young cultures. Hofmann's bacillus does not produce acid in glucose, or in saccharose media, and is thus further distinguished. The xerosis bacillus, obtained from the conjunctiva, also resembles the true diphtheria bacillus, but it produces acid both in glucose and in saccharose media.

The crucial test of the identity of the diphtheria organism is the prevention of the local or general action of an injected broth culture by the previous injection of diphtheria antitoxin into the test animal.

In the throat, diphtheria bacilli are often associated with streptococci, staphylococci, or the fusiform bacilli and spirilla described by Vincent. Of these, streptococci are most important, as cases of septicæmia have been found due to them. Diphtheria bacilli themselves rarely become disseminated in the blood stream but have been found in the cervical glands.

Pathology.—The constitutional disturbance caused by diphtheria is toxæmic, toxins but not bacilli being absorbed from the primary lesion, probably by the lymphatics. The extent, thickness, persistence and situation of the membrane determine the degree of toxæmia produced. In the formation of membrane, epithelial necrosis first occurs and is followed by inflammatory effusion from the subjacent tissues. This gives rise to the membrane in which stratified fibrin entangles epithelial cells, blood-cells and leucocytes. Nearly the whole of the process occurs outside the basement membrane. Bacilli are found in the false membrane and necrotic material, but not in the healthy tissues beneath. Recently formed membrane is firm in texture and has a glistening or somewhat gelatinous appearance. The tonsils are the common sites of the first membrane formation, but the faucial pillars, the soft palate, the pharynx, the epiglottis and the larynx may be implicated. Extension from the larynx along the trachea and main bronchi is not uncommon, but coherent membrane is rarely found in the bronchioles. Diph-

theritic membrane is much more firmly adherent to the mucous membrane of the fauces than to the epiglottis, the larynx and lower air passages. Its appearance in the cavity of the mouth, on the tongue or lips is rare, and even more rare is its occurrence in the cesophagus, stomach or small intestine. The conjunctiva and occasionally the vulva, or a cutaneous abrasion or a surgical wound may become infected. In this connection it must be remarked that streptococci, pneumococci, and the virus of glandular fever can on occasion produce false membrane.

Apart from the membrane the morbid appearances in diphtheria are not distinctive. The condition, however, of the heart muscle is of peculiar interest. Even in cases in which the myocardium appears healthy to the naked eye, special staining will show extensive infiltration of the muscle fibres with minute granules of mobilised fat. In advanced cases, patches of myocardial degeneration and perivascular aggregations of leucocytes become apparent. The valves escape. The cavities of the heart may be dilated, the muscle flaccid and friable, and intracardiac thrombi, some obviously antemortem, may be found in the recesses of the auricles and ventricles, particularly on the right side.

The stomach may be acutely inflamed, with mucosal hæmorrhages and erosions.

The chief lesion in the kidneys is a degeneration of the epithelium of the tubules, but glomerular involvement may also be present.

Broncho-pneumonia is not uncommon in extensive faucial and in laryngeal infections, it is usually due to secondary invaders. Emphysema or pulmonary collapse may occur where respiratory obstruction is severe, and massive collapse of the lung may result from paralysis of the respiratory muscles.

In the nervous system, the essential lesion is a parenchymatous degeneration of the peripheral nerves which is patchy in its distribution. Chromatolytic changes are found in the vagal nuclei and in the anterior cornual cells of the cord. The cerebro-spinal fluid is normal.

The lymphoid tissues of the body often show a reaction, Peyer's patches being swollen and the spleen slightly enlarged. The liver, too, may be swollen from venous stasis and show slight toxic degeneration of its cells.

Petechial hæmorrhages in the skin, serous membranes, heart wall, and diaphragm are characteristic of hæmorrhagic diphtheria. Extensive effusions of blood sometimes occur.

Symptoms.—The incubation period may not exceed 24 hours, more commonly it is 3 or 4 days, but a carrier may harbour virulent bacilli for a considerable time before showing signs of infection. The fauces are most often the site of the disease, next in frequency come the naso-pharynx, the nasal passages, the larynx and trachea. Infection of the genital mucous membrane and of wounds is exceptional and of the intact skin rare.

Faucial diphtheria may occur in any degree of severity, from a mild catarrhal inflammation, the identity of which is only established by bacteriological examination, to a widespread infection in which membrane invades not only the whole throat but also the naso-pharynx, nose, larynx, and, rarely, the mouth, either simultaneously or in succession.

Invasion may be characterised by malaise, headache, anorexia and soreness of the throat. Vomiting occurs occasionally and sometimes shivering.

rigor is rare. In children, the onset is particularly insidious, discovery of membrane often being the first intimation of the disease. The exudate in mild cases is limited to a patch on one or both tonsils, sometimes on the uvula or pillar of the fauces, sometimes on the soft palate. More rarely the posterior pharyngeal wall is first attacked. Special characteristics of the membrane are its elevation above the general surface, its well-defined edge, its glistening or pearl-grey colour, and its tendency to rapid spread. At first it is separable without bleeding, but later free oozing of blood occurs when it is forcibly detached. Multiple patches on the tonsils may, in the early stage, simulate follicular tonsillitis, but the patches tend to spread and fuse; limitation to one tonsil should always arouse suspicion of diphtheria.

Pyrexia is moderate or absent in mild infections, enlargement of the submandibular glands is slight, and early albuminuria so characteristic of grave attacks may be wanting.

When faucial diphtheria is severe it constitutes a very serious form of the disease with a high mortality. The grave form is more common in children than in adults and may develop very rapidly. The membrane is thick, tough, and adherent, sometimes much discoloured. It plasters the cedematous fauces and may extend widely over both aspects of the soft palate and on the pharyngeal wall. Nasal discharge points to implication of the naso-pharynx and nose. Rarely extension occurs along the hard palate and into the sulci at the sides of the tongue. Secondary invasion of the epiglottis and larynx is not uncommon. The cervical glands become swollen and tender, and periadenitis may extend and involve the neck in a collar of cellulitis (*bull neck*). The subcutaneous tissues may then undergo widespread necrosis and the skin become thinned and much discoloured. A brownish or bloody nasal discharge excoriates the nostrils and the upper lip. Nasal respiration is obstructed and deglutition difficult. The breath has a sickening odour, and the face is puffy or becomes ashen in colour. The skin is dry and the extremities cold. Slight general cutaneous cedema may make its appearance. The patient is restless and sleepless but apathetic. Bleeding is easily induced by interference with the edges of the membrane, and epistaxis may occur. Fever is not proportionate to the gravity of the disease; in the worst cases the temperature is subnormal. Albuminuria is usually profuse and the quantity of urine secreted may be very small, but uræmic symptoms are rare. A steady and progressive circulatory failure, characterised by a falling blood pressure and feebleness of the heart's sounds, is an ominous feature. The pulse may become soft, irregular or quite imperceptible. Respiration is rapid and shallow. Vomiting often sets in before the end. Broncho-pneumonia can rarely be recognised by physical signs, but is often present. Death may occur within a week of the onset; sometimes, however, under the influence of antitoxin the membrane clears and the faucial cedema subsides, but acute circulatory failure may still be imminent, death often occurring during the latter half of the second week. In those who escape, widespread paralysis is a common sequel.

Laryngeal diphtheria.—Infection of the larynx may be primary, but is usually a sequel of faucial infection. Essentially occurring in childhood, its frequency increases up to the fourth year of life, after which it progressively declines. The presence of membrane, even in the smallest amount, on the tonsils or fauces will afford a positive indication of the nature of the laryngitis.

Failing this a diagnosis is made by swabbing, not the tonsils, but the pharynx or larynx; but treatment must not be delayed pending the result. Hoarseness and croupy cough are early symptoms, soon followed by paroxysms of inspiratory dyspnoea due to laryngeal spasms, with characteristic stridor and recession of the chest wall. During the paroxysms the patient is agitated, sweating and perhaps cyanosed. The cough is loud and croupy. With relaxation of the spasm dyspnoea may cease and the child fall asleep from exhaustion. At first the paroxysms are mainly nocturnal, later they become more frequent and more prolonged, until finally obstruction is continuous and mechanical. Extraordinary recession of the sternum and lower ribs may then accompany the efforts to respire. The body assumes a leaden hue and death occurs from slow asphyxia. In rare instances the paroxysms of dyspnoea and cough culminate in the expulsion of membranous casts of the larynx, trachea or larger bronchi. The absence of toxæmic symptoms when membrane is limited to the larynx and lower air passages is very striking.

Laryngeal diphtheria may run its fatal course in a few days. In infants its duration may be less than 24 hours. In favourable cases the condition subsides under prompt treatment. Should obstruction persist after tracheotomy or intubation, the presence of membrane in the trachea or larger air passages should be suspected; when, however, the bronchioles are blocked, the character of the dyspnoea is quiet rather than violent. Laryngeal diphtheria in a mild chronic form is a rarity.

Nasal diphtheria.—A muco-purulent or blood-stained nasal discharge may be the only evidence of diphtheria in infants and fever convalescents. Infection may be naso-pharyngeal or purely nasal. The former is grave, as toxæmic symptoms may be pronounced, whilst localised nasal infection is more often benign and may be unilateral. In such cases a small patch of membrane may, perhaps, be found on the septum. Possible implication of the nasal accessory sinuses should be remembered. As already mentioned, bacilli from the nose may prove to be non-virulent. Foreign bodies in the nose have been found associated with persistent nasal diphtheria.

Conjunctival diphtheria is usually the result of direct inoculation, but may extend from the nose. It may simulate a mild, simple conjunctivitis, or membrane may form on the inner aspect of the lids. There is a grave form with extreme inflammatory infiltration of the conjunctiva which may lead to sloughing of the cornea and destruction of the eye.

Vulval, vaginal and preputial diphtheria.—Vulval infection may be secondary to diphtheria of the fauces, infection being conveyed by the fingers, or it may be primary. Sometimes it is seen in puerperal women. It is of insidious onset, and the membrane looks like a slough on the inner surface of one or both labia. The inguinal glands are enlarged, and confusion with noma, erysipelas, chancre or gonorrhoea is possible. Severe toxæmia may ensue. The vagina may be infected with the vulva. Preputial diphtheria may follow ritual circumcision. Infection of the puerperal uterus and of the male urethra is rare. Infection of the umbilicus may occur in the new-born.

Diphtheritic infection of wounds is not common, and membrane formation is not invariable. The wound may merely be dry and grey and the adjacent glands swollen. Bacteriological confirmation is necessary. Paralysis may be local in distribution.

Cutaneous diphtheria.—Slight infection of the macerated skin at the

margins of the nostrils and mouth is frequent and diphtheritic whitlow is not rare, the finger possibly being infected by sucking. Sometimes the raw surfaces left by eczema, herpes, or impetigo, become secondarily infected, and membrane may form, but skin diphtheria may occur without this distinctive sign. Gangrenous varicella and extensive gangrene allied to noma have also been attributed to the action of the diphtheria bacillus, as also have some veldt or desert sores (see p. 1151). Here again paralysis may have a strictly local incidence. Before skin cases are accepted as genuine, rigorous bacteriological proof is essential.

Septic diphtheria.—The ordinary grave case of diphtheria may be looked upon as toxæmic or malignant. The septic type of case is characterised by pulpy discoloured membrane and great inflammatory oedema at the site of infection, accompanied, it may be, by ulceration, cellulitis, or even gangrene. The adjacent lymph glands are much swollen, periaadenitis is marked and suppuration may ensue. Erythematous or measly rashes may appear on the extremities. Constitutional symptoms are severe and the prognosis grave, chiefly, it is alleged, because diphtheria antitoxin has no influence on the septic element, which may be a hæmolytic streptococcus.

Hæmorrhagic diphtheria.—Hæmorrhagic symptoms supervening during the acute stage indicate an infection of a severe type. Blood may ooze from the edges of the membrane, and epistaxis occur. This in itself is not necessarily serious, but the tendency to bleed may be more widespread, bruises appearing on the body and bleeding occurring around and along the track of the antitoxin needle. The conjunctivæ may become suffused with blood, and hæmorrhage may occur from the stomach or bowel. Hæmaturia is rare. In some cases small cutaneous petechiæ are the only evidence of the hæmorrhagic tendency, but they are of most sinister import.

Blood changes.—A polynuclear leucocytosis is common and reaches its acme at the height of the disease. Sometimes the red cells are in excess of normal and the specific gravity of the blood increased, indicating an oligæmia. Leucocytosis may be absent in very mild and also in very grave infections. The presence of myelocytes is also characteristic, and their appearance in large numbers indicates a severe toxæmia and a bad prognosis.

Complications.—The chief are circulatory failure, paralysis, albuminuria and pulmonary inflammations. Relapse sometimes occurs.

Acute circulatory failure is a justly dreaded occurrence. Apart from asphyxia and from respiratory paralysis it is responsible for all the deaths. In diphtheria, excluding the mildest cases and those in which respiratory obstruction exerts its modifying influence, there is from the first a progressive fall of blood pressure, the systolic readings being affected earlier than the diastolic. Recovery is very rare when the systolic reading falls below 65 mm. The fall in pressure is said to be accompanied by a fall in volume and increased concentration of the blood. Vascular relaxation is believed to account for the early fall in pressure, the effect of myocardial weakness appearing later. The condition culminates in attacks of acute circulatory failure. Where systematic pressure readings have not been taken, minor irregularities and intermissions of the heart's action often afford the first warning. True respiratory or sinus arrhythmia, which is so common in childhood and often is exaggerated in diphtheria, should not be confounded with the condition now under consideration. Tachycardia and bradycardia are

both disquieting signs. The heart sounds become modified, the first becoming short and soft and the second somewhat accentuated. Reduplication and gallop-rhythm may occur. Vomiting without obvious cause is always a danger signal. The characteristics of the acute attack are great irregularity and feebleness of the pulse, præcordial or epigastric pain, restlessness, rapid shallow respiration, slight cyanosis and a sub-normal temperature. The mind remains clear. Dilatation of the heart and increase in the size of the liver may be evident. Actual dropsy is rare, but sometimes slight œdema of the face, chest and feet appears. Albuminuria may supervene or, if already present, be much increased; partial suppression of urine occurs. Death often results with great suddenness, and should the first attack be survived, which is unlikely, a second or even a third may prove fatal. Rarely recovery ensues.

Death from circulatory failure is an early sequel of severe faucial infections, occurring at the end of the first or in the course of the second week. Cardiac failure occurring at a later stage of the disease is often associated with severe paralytic phenomena, and in some cases, at all events, is believed to be of nervous rather than myogenic origin. Extra systoles, heart-block and auricular fibrillation have at times been demonstrated. The absence of residual valvular or myocardial lesions after diphtheria is remarkable.

Diphtheritic paralysis occurs in from 15 to 20 per cent. of cases. It is more often localised than general, and rarely complete in degree. Palatine and ciliary paralysis are characteristic. Children suffer more frequently and more severely than adults. As a general rule the extent and severity of the palsy are proportional to the amount of membrane which was present. Exceptionally, paralysis of diphtheritic type occurs in the absence of recognised infection. The usual time of onset is the end of the third or beginning of the fourth week of the disease, but in grave infections it may even set in before the fauces are clear of membrane. Widespread paralysis, including a dangerous bulbar variety, rarely declares itself before the end of the fourth week, and paralysis of the ataxic type, which is rare, often does not appear until the second or even third month. For a detailed description see pages 1813-1815.

The limited form of diphtheritic paralysis is transitory, its duration being measured by days or weeks, but the more widespread paralysis may last for months or the best part of a year before recovery is complete.

Hemiplegia sometimes occurs in diphtheria and is due to occlusion of the middle cerebral artery, usually by an embolus. In most cases this paralysis is more or less permanent. Much more rarely an embolus from the heart lodges in a main artery of a limb, producing gangrene.

Albuminuria is of common occurrence, but in mild or doubtful cases its absence is not sufficient to negative the diagnosis. It is most likely to be found about the tenth day, but appears earlier and in greater quantity in grave cases. In those who recover, its presence is transitory and no grave damage to the kidneys results. At times casts and a little blood may be found in the urine, particularly in toxic or asphyxial cases. Acute circulatory failure greatly increases the albuminuria and may lead to suppression of urine. Acetone often appears in the urine during severe attacks.

Pulmonary Complications.—Bronchitis and broncho-pneumonia may accompany severe faucial diphtheria, but are more common when the larynx

is implicated. The cause is more often a secondary infection than the diphtheria bacillus. Febrile disturbance, great dyspnoea, cough, and lividity are the signs which should suggest implication of the lung. Auscultatory signs are often equivocal, owing to laryngeal obstruction or the presence of a tracheotomy tube. Massive collapse of the lungs may occur in paralytic patients and is often mistaken for acute circulatory failure, pneumonic consolidation or pleural effusion. Some degree of acute emphysema is usually present when the larynx is obstructed, and surgical emphysema of the mediastinal and subcutaneous tissues may follow a difficult tracheotomy. As sequelae of diphtheria, lobar pneumonia, pleural effusion and empyema are rare.

Otitis media is exceptional and seldom serious. In this respect it stands in sharp contrast to the otitis of scarlet fever. Diphtheria bacilli recovered from the discharge are often non-virulent (perhaps in 50 per cent. of the cases). Diphtheritic membrane is sometimes formed in the auditory meatus.

Relapse of diphtheria is rare. It occurs in little over 1 per cent. of the cases and usually is mild, the membrane being limited to the tonsils and rarely spreading to other parts.

Diagnosis.—Every inflamed throat, or nasal discharge, particularly in a child or fever patient, should be regarded with suspicion, and clinical diagnosis supplemented by bacteriological examination before antiseptics are applied. Definite membrane on one or both tonsils or adjacent parts of the throat is characteristic of diphtheria. Tonsillar inflammation, if accompanied by hoarseness or rhinorrhoea or albuminuria, is highly suggestive. Some diphtheritic throats are very cedematous and painful, but as a rule pallor of the mucous membrane and absence of pronounced fever and pain are striking features of the disease.

The differential diagnosis between scarlet fever and diphtheria is discussed on p. 75. Simple tonsillitis is usually bilateral, and the exudate, which is soft and crumbling rather than membranous, is follicular and limited to the surface of the tonsils. Pain, pyrexia and constitutional disturbance are more pronounced than in diphtheria, and the tongue is heavily coated.

Peritonsillar abscess is more characteristic of simple tonsillitis and the secondary tonsillitis of scarlet fever. It seldom occurs in diphtheria.

Vincent's angina may produce a greyish film of exudate on one or both tonsils, and even invade the adjacent parts of the faucial pillars and the soft palate, but the process is rather a shallow necrosis than a true membrane formation. Ulceration may be evident at the centre of the deposit; sometimes it is widespread and destructive. The mucous membrane of the gums and cheeks may also be attacked. The breath has a peculiar and offensive odour, but diagnosis should never be based on this alone. The large fusiform bacilli and spirilla described by Vincent can be demonstrated.

Double infections with diphtheria and Vincent's organisms are not at all rare. Thrush, which produces an exudate like milk curd, is recognised by detection of the characteristic mycelium. It is a disease of infants and greatly enfeebled adults.

Membranous angina may occur in glandular fever, leukaemia, or agranulocytosis. For the differentiation of these, blood-counts as well as throat swabbings are necessary.

Syphilis.—Both in adults with the acquired and children with the inherited

disease the inflamed throat of secondary syphilis is a cause of confusion. The throat is painful and full of mucous secretion. Filmey patches appear on the tonsils and pillars of the fauces. The tonsillar glands are swollen and indolent and there is little or no fever. The rapidity with which ulceration and perforation of the palate occur in some cases is striking. The diagnosis is made from the history, the presence of other signs of syphilis, failure to find diphtheria bacilli, a positive Wassermann reaction and prompt response to vigorous anti-syphilitic treatment.

Other conditions which simulate faucial diphtheria are erysipelatous inflammation, herpes of the soft palate and lesions due to steam, boiling fluids, caustics or tonsillectomy.

Laryngeal diphtheria.—Croupy cough, hoarseness, and stridor in a child will always suggest diphtheritic infection. Examination may show membrane on the fauces. By forcible depression of the base of the tongue with a spatula, the epiglottis may often be seen and membrane possibly recognised on its edge or surface. Rarely fragments of membrane are ejected on coughing, or there may be a history of contact with the disease. All doubtful cases should be treated freely with antitoxin, pending confirmation by examination of a swab taken from the pharynx as near the glottic aperture as possible.

Other forms of laryngitis have to be differentiated. They are (1) the laryngitis of early measles, distinguished by history, catarrhal symptoms, and Koplik's spots. (2) Simple catarrhal laryngitis; in this bacteriological examination is most essential. The voice may be hoarse, and the cough croupy; nocturnal spasms of dyspnoea may occur. Enlarged tonsils and adenoids are often present, and sometimes the history of previous attacks is obtained. (3) The glottic spasm of laryngismus stridulus is also definitely paroxysmal, but although the child crows the voice is not hoarse nor is the stridor persistent. Rickets, tetany and convulsions are the accompaniments in many cases.

Retro-pharyngeal abscess, when low down, produces considerable laryngeal obstruction. Digital examination of the back of the pharynx reveals its presence; sometimes the bulging may be seen on inspecting the fauces.

Rare causes of laryngeal obstruction are congenital laryngeal stridor, congenital syphilis, cedema of the glottis in renal disease, or resulting from inhalation of steam or other irritants, foreign bodies in the larynx, and papillomatous growths. These forms of obstruction are differentiated from diphtheria by the history, by careful inspection of the fauces, followed by digital examination, by general examination of the patient and by the negative results of bacteriological examination. In adults the laryngoscope will give useful information. Direct laryngoscopy is of great value.

Prognosis.—The important indications yielded by determination of the extent and position of the membrane have already been mentioned: the more extensive and more persistent this is, the greater is the risk of severe toxæmia. Cases where the membrane is limited to one, or to parts of both tonsils are likely to be mild; when both tonsils are completely covered the attack is more grave, but recovery is still probable; when the fauces and naso-pharynx are extensively involved, the outlook is very serious. The great mortality of laryngeal diphtheria is due to asphyxia and broncho-pneumonia, absorption of toxin from this region being small. Diphtheria limited to the nose and not involving the naso-pharynx has a low mortality.

Enlargement of the cervical glands is more or less proportional to the extent of the lesion in the fauces and naso-pharynx, and has the same prognostic importance. The efficiency of antitoxin treatment and the day of its first administration have a most important influence. The mortality is almost negligible when antitoxin is administered on the first day of the disease, but it increases progressively to 18 or 20 per cent. if administration is delayed to the fifth or subsequent days.

Age also has a great effect, the disease being very fatal to children in the first year of life, and much more serious in children under 5 than in those over that age. Septic attacks with much pallor, copious nasal discharge, considerable glandular enlargement and profuse albuminuria have a very bad prognosis.

Hæmorrhagic symptoms, other than slight bleeding from the edge of the membrane and possibly epistaxis, are grave; particularly so, minute cutaneous petechiæ. Cases such as these hardly ever survive. Repeated vomiting after the initial stage, and signs of acute circulatory failure are most ominous. The chief danger of paralysis, when this ensues early, is its association with acute circulatory failure, but paralysis of the bulbar type is in itself very fatal. Failure of the muscles of respiration and liability to broncho-pneumonia and pulmonary collapse constitute the chief dangers of generalised paralysis. If the patient survives, paralysis terminates in complete recovery, but hemiplegia, which is of vascular origin, may be permanent.

Treatment.—**PROPHYLACTIC.**—Convalescents should be isolated for not less than 4 weeks from the commencement of the disease, or until three negative bacteriological examinations at intervals of a week have been obtained. The presence of inflammatory conditions or discharges from the throat, nose, eyes or ears is an indication for further detention. Skin eruptions and whitlows should be carefully treated.

The period of quarantine advised is 12 days. This may be supplemented or replaced by bacteriological examinations. Children from an infected house should not be allowed to attend school until proved free from infection. Contacts in the home or school often become carriers, and should also be bacteriologically examined. Clothing and utensils which have been in contact with the sick should, of course, be disinfected.

When diphtheria breaks out, contacts should be examined for unhealthy conditions of throat, nose, ears or skin, and bacteriological examination made in all instances, if possible. Opinion with regard to the desirability of prophylactic injections of antitoxin is not unanimous. The *symptoms* of diphtheria may be prevented in contacts by the injection of 500 units of antitoxin, but this method fails if the subject is already incubating the disease, and only affords protection to others for some 3 or 4 weeks. It should be realised that antitoxin does not prevent *infection*, but only the toxic results of infection. It militates against active immunisation, and may produce a condition of hypersensitiveness to serum, which may have to be used subsequently.

For these reasons, the best authorities are against prophylactic injections of antitoxin in contacts and in favour of repeated examinations for signs of development of the disease, when antitoxin can be administered at once. Meantime, immunisation of susceptible contacts (*vide infra*) can be initiated, since there appears to be no negative phase induced.

In the Schick test we have a means of determining whether an individual is susceptible to diphtheria. If a local inflammatory induration from 1 to 2 cm. in diameter follows the injection of a minute quantity of diphtheria toxin into the skin, susceptibility to the infection is indicated. One-fiftieth of the minimum lethal dose (M.L.D.) of toxin for a guinea-pig of 250 grammes weight, in 0.2 c.c. of normal saline is the standard dose. At the same time, but at another spot, an intradermic injection of heated, and therefore inactive, toxin is made, to discount a "pseudo" reaction due to the foreign protein in the solution of toxin. The absence of a reaction to the active toxin generally indicates the presence of more than one two-hundredth of a unit of antitoxin per c.c. in the blood, and is a sign of immunity. The injections are usually made into the skin of the forearms. The reaction takes 24 to 36 hours to develop, and another week to subside. Four types of reaction are possible: (1) Negative, (2) Positive, (3) Negative and Pseudo, and (4) Combined Positive and Pseudo. These must be discriminated with care. The best time for reading the test is 36 hours after injection, and again at the end of a week when false reactions will have faded and late positive reactions will be detected.

For immunisation, diphtheria toxin, guarded by antitoxin, was originally used. Later, toxin, converted to toxoid by incubation with formalin (*anatoxine*), replaced this. Toxoid-antitoxin floccules, precipitated by interaction of toxoid and antitoxin produce little or no reaction and are effective. For the immunisation of children, alum-precipitated toxoid (A.P.T.) is now recommended. Two doses (of 0.5 c.c.) are given intramuscularly, with an interval of 4 weeks between, the first dose acting both as an antigen and as a detector of sensitive individuals. For adults, who are more liable than children to reactions, toxoid-antitoxin floccules (T.A.F.) are preferable, three injections (1 c.c., 1 c.c. and 1.5 c.c.) being administered, with intervals between them of 3 or 4 weeks. Susceptibility to reaction may be detected by intradermal injection of 0.2 c.c. of diluted toxoid (Moloney test). The development of active immunity takes about 6 weeks. This immunity is protracted, but its exact duration cannot yet be specified. Most children under 6 years are susceptible and the ideal time for immunisation is in the pre-school period, after the first year of life. At the beginning of school life a supplementary dose of 0.5 c.c. is recommended. When the proportion of vaccinated children in a community reaches 70 to 80 per cent. a great reduction of incidence of diphtheria, and of carriers, perhaps to zero, may be expected.

When dealing with outbreaks of diphtheria in wards or institutions, swabs should be taken from the throats and noses of the inmates, and Schick tests performed. The negative reactors are then isolated. They will probably include a dangerous chronic carrier as proved by the virulence test. The positive reactors may be immunised with A.P.T. Virulent bacilli in the Schick positive group indicate precocious carriers who will soon sicken with the disease.

Chronic carriers are a great source of difficulty. The bacilli cannot be eradicated by local application to the throat or by the administration of antitoxin or vaccines. If the tonsils are unhealthy, they should be enucleated and adenoids removed; this is often successful. In nasal carriers when streptococci co-exist the insufflation of sulphonamide powder twice daily for 8 days has seemed effective. Carriers should spend as much time in the

fresh air and sunlight as possible. Before condemning a carrier to isolation, the virulence of the organisms should be tested and confirmed.

CURATIVE.—The patient should be isolated and strict recumbency enjoined. Diphtheria antitoxin must be injected without delay, the result of bacteriological examination not being awaited in any case in which the diagnosis is reasonably certain. Although antitoxin can neutralise circulating toxin, it is much less effective against toxin which has become fixed in the cells of the body. It is therefore very important the patient should receive the first dose of serum not later than the third day of the disease; the earlier it is given the better the result, but at whatever stage the presence of membrane indicates prompt dosage. The amount required depends, not on the age, but on the duration of the disease, the extent of the membrane and the degree of toxæmia. For mild cases on the first or second day 8000 units are sufficient; in more severe cases the dose should be 20,000 units. In severe faucial and naso-pharyngeal diphtheria and in infections of the larynx, 20,000 units should be the initial dose, repeated in 12 hours if the membrane still shows a disposition to extend, or the laryngeal symptoms are not relieved. Cases coming under observation after the third day of illness require larger doses than those seen earlier. In very severe infections and those complicated by pulmonary lesions, enormous doses have been recommended. The advantage of these is doubtful.

Intramuscular injection of antitoxin is more effectual than subcutaneous. In severe, advanced, and hæmorrhagic infections, the antitoxin should be given intravenously, undiluted and at blood heat. Injection should be very slow, through a fine needle. The patient is then wrapped in warm blankets, hot water bottles applied, and the foot of the bed raised, since rigor and collapse may follow. Fifty thousand or more units may be given in this way, followed by intravenous injection of 20 grammes of anhydrous dextrose in the form of a 50 per cent. solution in normal saline, supplemented by 20,000 units of antitoxin intramuscularly into the buttock or outer side of the thigh. In cases which do not respond the injection is repeated after 12 hours.

Antitoxin treatment may be followed by certain sequelæ due to horse serum. These are less frequent when concentrated or protein-digest antitoxins are used. They usually occur a week or more after injection and take the form of erythematous, morbilliform, or urticarial eruptions, appearing first in the vicinity of the puncture. Fever, vomiting, arthritic pains or slight joint effusions may accompany the rash. The tonsils may again become inflamed (*angina redux*) and albuminuria may occur. The rashes and other symptoms are transient but may recur. Aspirin often affords much relief, and the cutaneous irritation may be allayed by weak carbolic lotions. On rare occasions rigor, dyspnoea and collapse follow the injection immediately, and death has been known to occur. These symptoms are anaphylactic in nature and may occur if the patient has been sensitised by injection of serum a few weeks previously, or quite apart from this. Asthmatics are said to be particularly liable to them. When it is necessary to administer antitoxin in such circumstances, a preliminary injection of 5 minims should be given subcutaneously and the effect watched, or an intradermic test made. If no symptoms occur within an hour the full injection may be employed, otherwise desensitisation is necessary (see p. 7).

Absolute recumbency is essential in the treatment of diphtheria. For

the mildest case a fortnight is not too long, in the average case at least a month, and for severe infections longer. When the patient is first allowed to sit up in bed the effect on the pulse should be carefully noted. No patient should be allowed to sit up whose pulse is irregular or who has recently vomited. The detection of paralytic symptoms is also an indication for rest.

Local applications to the fauces and nose are of minor importance. In cases characterised by fetor the free chlorine lotion is of use. When douching is resisted it is better to omit it altogether.

In laryngeal diphtheria prompt administration of antitoxin and the use of a steam tent will generally obviate the necessity of operative interference; but tracheotomy, intubation or laryngeal aspiration should not be postponed, if restlessness, dyspnoea and recession of the chest wall are present, or paroxysmal dyspnoea has supervened.

Intubation is suitable for the milder type of case, but constant skilled supervision is necessary, as the tube may be ejected. As a rule, tracheotomy is preferable, especially if the fauces and naso-pharynx are much involved. Tracheotomy as a sequel to intubation has a very high mortality on account of the class of case in which it becomes necessary. After tracheotomy or intubation the patient is usually placed in a steam tent and the arms secured by light splints or other means. Cough on swallowing is obviated by using thickened foods or by nasal feeding. A method of feeding with the head lying lower than the body is often successful in intubated patients. If all goes well an attempt should be made to dispense with the tracheotomy or intubation tube on the third day, sometimes even sooner. Patients must be watched constantly when the tube is first removed. In cases where the tracheotomy is dry and no secretion occurs, an alkaline spray is useful.

Circulatory failure is treated by removing all pillows, raising the foot of the bed on blocks and applying a binder to the abdomen. The most absolute rest and perfect quietude are essential. A combination of atropine, strychnine and adrenaline has the best reputation as a circulatory stimulant in these cases (atropine sulphate, gr. $\frac{1}{100}$; strychnine sulphate, gr. $\frac{1}{100}$; adrenaline solution, 1 in 1000, min. 5). The solution is made up to 10 minims with sterile water and injected every 4 hours or more often if necessary. At the same time, as vomiting often precludes feeding by the mouth, a 5 per cent. solution of glucose in hot normal saline should be given by the bowel. Other circulatory stimulants and brandy are also advocated. When marked acetonaemia is present, 10 grains of sodium bicarbonate dissolved in 1 ounce of water should be given by mouth or rectum every 4 hours.

Paralysis calls for careful nursing and feeding, with avoidance of muscular exertion, but patients with only palatine paralysis may be allowed up after 10 days if the condition is stationary. Massage and electricity may be useful during convalescence, but should be avoided in the early stages. Hypodermic injection of strychnine is possibly of some use. The administration of vitamin B₁ (aneurine hydrochloride; thiamine hydrochloride, U.S.P.) is said to expedite recovery. The daily administration of antitoxin in doses of 1000 to 2000 units is advocated, but is of very doubtful utility. Extensive respiratory paralysis necessitates artificial respiration with a Drinker or Bragg-Paul apparatus. Active collapse of the lung in diphtheria may be

mistaken for acute circulatory failure if its special diagnostic signs are not borne in mind.

During the acute stage of diphtheria and also when albuminuria is present, milk, glucose mixtures and fruit juices are the best food. Solids may be allowed quite early in convalescence. When swallowing provokes coughing, the milk should be thickened with isinglass or cornflour. When pharyngeal paralysis is present, the patient should be fed by rectum, or better, through a large soft œsophageal tube or by nasal catheter.

The occurrence of anaphylaxis after injection of antitoxin is treated by injection of adrenaline, and by artificial respiration; by some adrenaline is given before injection of serum, as a prophylactic.

WHOOPIING-COUGH

Synonym.—Pertussis.

Definition.—An acute specific disease of high infectivity, characterised by catarrh of the respiratory tract, with periodically recurrent laryngeal spasms of distinctive type and other signs of abnormal nervous excitability.

Ætiology.—Whooping-cough is mainly a disease of temperate climates, being rarer and less severe in hot countries. Spring and autumn are the seasons of its maximum prevalence, occasionally in epidemic form, and also of its greatest mortality, chiefly owing to respiratory complications; but the disease may also occur in the warmer months. It is more prevalent in cities and industrial centres than in the population of rural districts. The heaviest incidence of whooping-cough is in the first five years of life, with a dangerous tendency to attack children under two. After ten years of age attacks are comparatively uncommon, but are by no means unknown in susceptible adults even over 60, and, in some instances, over 80 years. The *fœtus in utero* has been known to contract the infection from its mother, as also may the new-born child. More females than males are attacked. The frequency with which whooping-cough follows an attack of measles is noteworthy. It may occasionally be a precursor of laryngeal diphtheria.

Infectivity is greatest during the catarrhal and early paroxysmal stages; but its exact duration is variable. On rare occasions convalescents are said to have acted as carriers of the disease.

The infection is usually conveyed by the mucous droplets expelled by the cough. Since the bacillus can resist drying for several weeks the infection may lurk in rooms and fomites, but this is uncommon. One attack almost invariably confers lifelong immunity.

BACTERIOLOGY.—Of the various organisms which have been alleged to be the causal agents, the bacillus of Bordet and Gengou (*Hæmophilus pertussis*) has the strongest claims to acceptance. This is a minute, slender rod closely allied to the bacilli of the influenza group. It is Gram-negative, and only flourishes on artificial media which contain blood or serum. It grows best at blood heat. The bacilli swarm on the ciliated epithelium of the air passages and cultures are most easily obtained from the small pellets of viscid mucus which are expectorated at the end of a paroxysm of coughing. The blood of convalescents agglutinates the bacilli.

There are no post-mortem appearances which are distinctive, the changes

found after death being due to complications. Of these, congestion of the air-passages and broncho-pneumonia are the most common, and are accompanied by general acute vesicular emphysema. The tracheo-bronchial lymph glands are usually soft and swollen.

The paroxysmal cough is attributed to hyperæsthesia of the respiratory mucous membrane with heightened excitability of the vagus nerve.

Symptoms.—The incubation period is difficult to fix with accuracy, owing to the insidious nature of the onset and the delayed appearance of the characteristic whoop, but it is probably 13 to 15 days. Extremes of 3 days and over 3 weeks have been claimed. During a typical attack three stages may be recognised—catarrhal, paroxysmal, and convalescent.

The catarrhal stage lasts from seven days to a fortnight—it is febrile, and resembles a somewhat severe respiratory catarrh; but the cough is more troublesome and bronchitic signs ill-marked. Recognition of the disease at this, the most infectious, stage is difficult unless the patient is known to have been exposed to the infection. Suggestive signs towards the end of the period are a tendency of the cough to assume a paroxysmal character, with greater severity at night, giving rise to suffusion of the face and occasionally to retching or vomiting. Bacteriological investigation by swab or cough plate and the detection of lymphocytosis will assist early diagnosis.

When the paroxysmal stage is reached the disease is unmistakable. Fever will usually have subsided; but the cough occurs in paroxysmal bouts, often spontaneous, but frequently the result of external stimuli, such as excitement, draughts, the ingestion of food or examination of the throat. Several paroxysms may occur in quick succession with longer or shorter intervening periods of freedom. The victim senses the cough impending, and may attempt to suppress it. If lying in bed a child will sit up, or if about may run to mother or nurse. A brief, deep inspiration is followed by a rapid succession of short coughs, with open mouth and protruded tongue, which are continued until the chest is almost emptied of air. The face becomes congested or livid, the superficial veins are engorged, and the eyes fill with tears. The eyeballs protrude, the skin is bathed in sweat, and suffocation appears imminent; but relief is suddenly afforded by relaxation of the laryngeal spasm and the occurrence of the whoop, a long-drawn crowing inspiration, which refills the lungs with air. The paroxysm then recurs, and may be repeated several times, leaving the child perspiring and exhausted. The bout often terminates with the discharge from the air-passages of a pellet of viscid, transparent mucus. A quantity of thin sticky secretion, which is sometimes blood-stained, may also flow from the mouth and nose. During the fits of coughing, which often last for 2 or 3 minutes, the child may faint or become convulsed and insensible. The contents of the stomach are often ejected, and the urine may be voided; in some instances incontinence of fæces occurs. Epistaxis is not uncommon in the more severe attacks. Subconjunctival hæmorrhage may occur, and petechiæ appear in the skin of the eyelids, root of the neck and other parts. Rarely the membrana tympani is ruptured, and blood escapes from the ear. In infants asphyxia may occur.

In the early paroxysmal stage the cough is only occasional, but its frequency soon increases, and in a case of moderate severity from 15 to 20 paroxysms occur in the 24 hours; in some attacks, however, they are much

more numerous. They are characteristically most frequent and most severe at night.

Physical examination of the chest at this stage will still reveal signs of diffuse bronchitis; but this is now accompanied by a greater or less degree of acute emphysema and a moderate degree of abdominal distension is not uncommon. The forcible protrusion of the tongue over the lower incisor teeth often produces a shallow ulcer on the *frænum linguæ*.

The duration of the paroxysmal stage is from 3 to 10 weeks, and after this convalescence begins. Whooping-cough is more prolonged in winter than in summer, and its duration is increased if complications ensue. After the whoop has ceased a fresh attack of respiratory catarrh may cause it to reappear; but this should not properly be regarded as a relapse, and does not render the patient again infectious.

A leucocytosis occurs even in the early catarrhal stage. The lymphocytes are increased out of proportion to the other cells; a typical count would be 15,000 to 25,000 white cells per c.mm. with from 50 to 70 per cent. lymphocytes. (At the age of 6 months, in health, the proportion of lymphocytes is 57 per cent. and at 2 years 53 per cent.) Myelocytes may also appear. The leucocytosis is increased after each paroxysm of coughing, and the highest counts to be found during convulsions. The supervention of pneumonia increases the polymorphonuclear cells.

Course.—Attacks vary in their severity and duration. Mild infections may run their whole course in a week or two, and the whoop may be absent, whilst severe ones may last several months. As mentioned above, the number of paroxysms in 24 hours is some measure of the severity. The danger of supervention of complications is proportional to the severity of the attack.

When whooping-cough occurs in the adult the disease may be characterised by violent fits of coughing with a sense of impending suffocation but no whoop. Cyanosis, vomiting, and even temporary attacks of unconsciousness may occur and subcutaneous ecchymoses appear. The legs may become oedematous and muscle rupture may ensue from the violence of the cough, which retains its paroxysmal character and nocturnal severity. In infants, too, the whoop may be very imperfectly developed.

Complications.—These belong mainly to the paroxysmal stage of the disease—they are partly mechanical and partly inflammatory in nature. The most serious are excessive vomiting, broncho-pneumonia and convulsions.

When the paroxysms of coughing are frequent and severe, excessive vomiting may lead to great emaciation and exhaustion. Diarrhoea and ileocolitis may also occur, mainly in younger children, and during the summer months.

Pulmonary complications are frequent, and are more common during the winter. A mild bronchitis with general, but temporary, acute emphysema is the rule, and is of but little moment. Capillary bronchitis or broncho-pneumonia, with pulmonary collapse, is much more serious. It usually occurs at the height of the paroxysmal stage, and is responsible for two-thirds of the deaths. In hospital practice its incidence is about 12 per cent. Interstitial emphysema of the lung may result from rupture of an air cell during coughing, but is only likely to be recognised when it overflows into the root of the neck and the connective tissue of the chest wall. Pneumothorax may

occur. Bronchiolectasis is an occasional sequel of the disease. In the adult an asthmatic tendency may ensue.

A single convulsion may prove of little importance, but convulsive states in the form of *whooping-cough eclampsia* constitute a deadly but rare complication, which is seen chiefly in infants and young children. The convulsions occur after prolonged paroxysms of coughing or as a terminal event, but on occasions they may precede a paroxysm or occur in the intervals. Their cause is much disputed. It is tempting to associate them with the encephalitis of other infectious diseases, but K. Neuburger attributes these and certain other nervous complications to air-embolisms which produces ischæmic central necroses. Vascular spasm has also been suggested as the cause. The cerebro-spinal fluid may be under tension with a slight increase in mononuclear cells.

Coma or paralysis of varying duration and extent may follow convulsions. Transient or permanent hemiplegia; aphasia; paralysis of ocular muscles; or defects of sight, hearing and intelligence sometimes supervene; and bulbar paralysis and polyneuritis have been recorded. Defect in vision is sometimes due to retinal hæmorrhage or detachment, but choked disc may also occur.

The strain of the recurrent paroxysms of coughing may induce dilatation of the right ventricle of the heart, subconjunctival hæmorrhages, cutaneous petechiæ, epistaxis, bleeding from the mouth or ears, hæmoptysis, and hæmorrhage on the surface or less commonly in the substance of the brain. Other results are the appearances of herniæ and prolapse of the rectum.

True nephritis is rare, but albuminuria may appear. Glycosuria is occasionally found.

An unhealthy condition of the naso-pharynx may persist after the cough has subsided, and no other disease except measles has such a bad reputation as a forerunner of tuberculosis.

Diagnosis.—In the absence of known exposure to infection, diagnosis may be impossible until the whoop is heard; but the significance of a paroxysmal cough, worse at night and terminating in retching or vomiting, should not be overlooked. The disproportion between the violence of the cough and the accompanying physical signs in the chest is also noteworthy. When broncho-pneumonia does supervene the whoop may cease. In infants the cough may be paroxysmal and asphyxiating, but the whoop not developed; in such cases, as also in adults when the whoop is absent, the diagnosis may be cleared up by the occurrence of infection in contacts.

Bacteriological diagnosis may be effected by post-nasal or laryngeal swabbing or, better, by receiving the invisible droplets ejected during a natural paroxysm of coughing on a modified Bordet-Gengou culture medium in a Petri dish, held 6 inches in front of the mouth. The medium consists of defibrinated blood-agar, human blood being used by preference. The growth should be recognisable in 48 to 72 hours as small glistening colonies of minute ovoid, Gram-negative rods, frequently paired. More than one exposure may be necessary especially in infants. A negative result does not necessarily exclude whooping-cough. The bacteriological method may also be applied to determine the cessation of infectivity, three negative results on successive days being accepted as satisfactory.

The spasmodic cough of bronchial gland irritation, of adenoids, or that induced by a foreign body in a bronchus, is apt to be paroxysmal, but the whoop is wanting. The same observation applies to the obstinately recurrent coughs of influenza and bronchiolectasis. In children, laryngeal inflammation of catarrhal or of syphilitic origin may induce paroxysms of cough and laryngeal spasms, but the tone of the cough at once indicates its laryngeal origin. Conversely, whooping-cough in its early stages, if accompanied by an unusual amount of laryngeal catarrh, may be confused with the laryngitis of measles or of diphtheria. In adults the laryngeal crises of tabes or coughing induced by thoracic aneurysms or intra-thoracic growths occasionally suggest whooping-cough.

In the catarrhal stage the malaise, cough, pyrexia and slight fullness of the abdomen with perhaps some irregularity of the bowels, may arouse unfounded suspicions of early general tuberculosis.

The leucocytosis of whooping-cough, which is considerable in the early stages, may prove of assistance in the early diagnosis of the disease, especially if combined with sputa teeming with slender Gram-negative organisms like influenza bacilli and a normal erythrocyte sedimentation rate. The count should, of course, be compared with that normal for the child's age. An authentic history of a previous attack puts whooping-cough for all practical purposes out of court, second attacks being excessively rare.

The presence of the sublingual ulcer is only to be expected after the incisors have appeared. Occasionally it is seen in other conditions of persistent cough.

Prognosis.—Whooping-cough is a much more serious malady among the families of the poor, and in those suffering from malnutrition, rickets, tuberculosis, or a predisposition to chest troubles, than it is to healthy well-fed children. Apart from this, age constitutes the most important prognostic factor. Infants and children under 3 years of age suffer a considerable mortality, which for the first 12 months of life may be as high as 25 per cent. The mortality decreases rapidly after the third year, and after 10 years of age is insignificant. Broncho-pneumonia causes most of the deaths, occurring chiefly in the winter months. In the summer, ileo-colitis comes into prominence.

Convulsions, especially if repeated, are of grave omen. Death at times occurs suddenly from asphyxia due to sustained laryngeal spasm, or from heart failure, intracranial hæmorrhage or, it is suggested, air-embolism. When tuberculous lesions are present these may be stirred into activity by the infection, and especial care is necessary.

A cautious prognosis should be given with regard to paralytic sequels, since in a number of cases these prove permanent.

Treatment.—Isolation should be enforced and trustworthy attendants provided. Free ventilation with abundance of fresh air gives better results than confinement in a close room and the inhalation of medicated vapours. In the absence of fever, older patients may be allowed up and out as much as possible, provided isolation can be maintained. In suitable weather continuous open-air treatment may be adopted even for those patients who are confined to their beds. It is especially valuable in broncho-pneumonia. A light binder should support the abdomen, and the clothing be loose and not too heavy. The diet should be light and digestible, excess of starchy and

saccharine food being avoided. When vomiting is persistent it is a good rule to administer food in small quantities shortly after the paroxysms of coughing. Overloading the stomach may aggravate the cough. A diet of milk or whey may be considered in some instances. Orange juice with glucose may be given freely. Rectal feeding is very unsatisfactory. The chest may be rubbed as a routine with some stimulating liniment.

There is no specific remedy for whooping-cough, although quinine or euquinine in large doses have been recommended. During the catarrhal stage simple expectorant mixtures are sufficient, and later the paroxysms may be modified by such sedatives as belladonna, phenazone, bromoform, paregoric, codeine and heroin, all of which have their advocates. Tincture of belladonna in increasing doses (2 or 3 minims four-hourly cautiously increased until the pupils are widely dilated) and phenazone are the most generally useful; the latter may be given to a child in doses of 1 or 2 grains with small doses of potassium iodide and expectorants every 4 to 6 hours. Remarkable amelioration of the cough and vomiting may be effected by the use of heavy doses of sodium bicarbonate, the urine being made and kept fully alkaline. It is claimed that intramuscular injections of ether in doses of 1 or 2 c.c. given every 2 days reduce the number of paroxysms. Vaccine treatment with the Bordet-Gengou bacillus is still on its trial. Its prophylactic is greater than its curative value. Smooth, recent, virulent strains are essential. At weekly intervals three or four injections are given, starting with 10,000 million organisms and rising to 30,000 million. Attention should be paid to the condition of the nose and throat, and adenoids removed as soon as possible in convalescence, since they tend to maintain the cough. As after treatment, tonics and a change to the seaside are advisable.

Complications should be treated on general lines. Obstinate vomiting needs careful feeding, and phenobarbitone one-sixth to one-quarter grain 3 times a day, or intramuscular injections of soluble phenobarbitone (gardenal sodium, luminal sodium). Gastric lavage with 0.6 per cent. solution of sodium bicarbonate may help. Asphyxial attacks may be treated by pushing forward the lower jaw and applying artificial respiration. Inhalation of CO_2 is said to be of good effect. Intubation has been practised in some very severe cases. Convulsions call for the mustard-bath or hot pack, with an enema of paraldehyde (3j or 3ij) in olive oil. A whiff of chloroform may give relief, and sometimes lumbar puncture with free escape of cerebro-spinal fluid is effective. In broncho-pneumonia sulphonamides may prove useful.

The injection of the serum of convalescents, on the same lines as in measles and in similar doses (*q.v.*), has been advocated as a prophylactic but has proved disappointing.

Although the infectivity of the paroxysmal stage, especially of its latter part, is problematical, patients should be isolated for 5 weeks from the commencement of the whoop, provided the paroxysmal cough and whoop have ceased for a fortnight; or, better, until the infecting organism has disappeared, which may occur after 3 weeks of illness, or a week or two later. The quarantine period for non-immune contacts is 21 days. Disinfection of rooms and clothing is desirable.

CHARLES R. BOX,

BACILLARY DYSENTERY

Bacillary dysentery is one of the most important war diseases, and in the past has been associated with a very high incidence and serious mortality. In the war of 1914-1918 it caused much sickness and death in the British Armies campaigning in Africa and Macedonia. In the present war the incidence has been markedly reduced, owing mainly to (1) a higher standard of field and camp sanitation, (2) the education of medical personnel, combatant officers and other ranks regarding the fly menace and need for water sterilisation, and (3) the introduction of specific drugs, like sulphaguanidine, which cure the disease.

Definition.—An acute inflammation of the colon, often associated with superficial ulceration of the mucosa and occasionally with extensive coagulation necrosis, caused by specific dysentery bacilli. The disease is characterised clinically by a sudden onset, with colicky abdominal pain, followed by urgent diarrhoea, malaise, vomiting, headache, muscular pains and fever; in the early stages the stools may be brown, watery and contain flakes of mucus; later, they are mainly composed of glairy mucus, perhaps admixed with blood or yellowish muco-pus. Many cases of dysentery, however, are so mild that they are frequently regarded as diarrhoea.

Ætiology.—Dysentery bacilli may give rise to sporadic cases, outbreaks, or definite epidemics. No country is exempt and natives and Europeans of all ages and both sexes are susceptible. In England and Europe, Flexner and Sonne dysentery bacilli may cause outbreaks in military barracks, prisons and asylums, and along with Morgan's bacillus No. 1 are responsible for certain outbreaks of summer diarrhoea in children. Filth, overcrowding, malnutrition and intercurrent disease predispose, notably when sanitary conditions are bad, as in prison camps. Dysentery is common in warm climates, especially during the early summer, rainy season and autumn months, and the epidemic wave closely follows the fly rise. It is most frequent where sanitation is defective, flies prevalent, and garbage disposal inadequate. Dysentery is spread by (1) faecal pollution of water, or (2) contamination of food, either directly from a carrier or indirectly by faecal-feeding flies. In some countries, such as the Netherlands East Indies, where the natives defæcate directly into flowing water or streams running into rivers, the disease is predominantly water-borne and prevention consists essentially in water sterilisation. In the Middle East, however, infection is mainly fly borne. Uncooked vegetables, particularly salads, are always suspect, as human excrement is so often employed as manure. Cooks and food-handlers who are carriers are also a potent source of infection. Recent technical advances in culturing dysentery bacilli have shown that a larger proportion of dysentery cases become carriers than was formerly thought.

Shiga (1898), in Japan, first discovered *B. dysenteriae* Shiga, which is a most virulent organism producing a true exotoxin. This was rapidly followed by the isolation of several other strains of dysentery bacilli. Boyd, who has recently reclassified the organisms causing bacillary dysentery, recognises two non-mannitol fermenting bacilli, *B. dysenteriae* Shiga and *B. dysenteriae* Schmitz. Of the mannitol fermenting dysentery bacilli there is *B. dysenteriae* Sonne, which is a late lactose fermentor, and two groups of non-lactose ferment-

ing organisms which include six types of *B. dysenteriae* Flexner, *i.e.*, I, II, III, IV, V and VI, and three types of *B. dysenteriae* Boyd, *i.e.*, I, II and III. The latter types have been found in India, the Middle East and New Guinea, and probably have a still wider geographical distribution. More than half the dysentery in warm climates is caused by organisms of the Flexner-Boyd group. In the Middle East, *E. histolytica* accounted for 12·3 per cent., *B. dysenteriae* Shiga for 15·8 per cent., and Flexner-Boyd I for 52·3 per cent. of Army cases in 1941.

Pathology.—While the naked-eye pathology of fatal cases is well known, the macroscopic appearances of the bowel in non-fatal cases can only be studied during sigmoidoscopic examinations of the rectum and pelvic colon. Combined studies have shown a wide range of pathological lesions, including (1) transient catarrhal inflammation with hyperæmia associated with increased mucoid secretion but without ulceration; (2) more severe generalised inflammation with hyperæmia, cedema, scattered hæmorrhages and localised areas of coagulation necrosis of the mucosa, exfoliation of which subsequently leads to superficial ulcers covered with muco-pus; and (3) widespread coagulation necrosis of the mucosa, which, in fulminating cases, is characterised by a greyish-white or greenish gangrenous membrane. Cases dying in the acute phase of the disease often show extensive ulceration, which may involve the whole mucosa, and sometimes the terminal 12 inches of the ileum as well; in others maximal lesions are found in the rectum, sigmoid colon and cæcum. Fatal cases have also shown hæmorrhagic inflammation and swelling of the meso-colonic lymph glands, parenchymatous degeneration of the liver and kidneys, and central necrosis of the supra-renal glands. In *subacute* cases, with slowly resolving dysentery (1 to 2 months), the mucosa may remain inflamed and present widely scattered ulcers and erosions covered with muco-pus; in other instances only superficial ulcers remain, the intervening mucosal surface appearing normal.

In severe *chronic bacillary* cases, lasting three months or longer, two types of lesions may be found: (1) well defined superficial oval or circular ulcers up to 1 cm. in diameter scattered over an otherwise healthy-looking mucosa; and (2) the bowel surface composed largely of granulation tissue, which bleeds readily and closely simulates ulcerative colitis. The walls are thickened and contracted, so that the bowel resembles a rigid tube. Rogers found that chronic bacillary dysentery mainly involved the rectum, sigmoid and ascending colon.

Symptoms.—The incubation period is from 1 to 7 days. The clinical features vary with the resistance and age of the patient, and the type of the invading organism. Thus, Flexner-Boyd and Sonne infections are often mild and Shiga infections frequently severe. In infants, however, Flexner infections may be rapidly fatal, greenish fluid stools containing typical bacillary exudate being passed.

Acute, subacute, and chronic clinical types of dysentery may be encountered.

ACUTE DYSENTERY

The Flexner-Boyd Group.—Many cases are of mild catarrhal type, and, as a rule, symptoms of severe toxæmia and dehydration do not develop.

The onset is characterised by colicky abdominal pain, followed by urgent

diarrhoea. Nausea, transient vomiting, headache, shivery feelings and aching in the limbs may accompany, follow or precede the onset of abdominal symptoms. The presence of mild prodromal toxic features preceding the onset of diarrhoea affords no index to the severity of the infection. Fever is present soon after the onset in most cases. Examination reveals diffuse tenderness, most marked over the right or left iliac fossa, or the upper part of the abdomen. The abdominal pain is predominantly colicky in character. Between the paroxysms the patient may get relief or complain of a persistent dull ache. Tenesmus due to rectal spasm is less frequent in mild than in severe infections.

Diarrhoea is generally most intense on the first and second day of attack, the stools as a rule decreasing in number thereafter, but in some cases the maximum number is reached on the third, fourth or fifth day. At first the stools are fairly copious and watery, but, if looked for, flakes of mucous and blood will generally be found. Most cases of febrile diarrhoea in which numerous liquid stools are passed are bacillary dysentery. As the condition develops, the stools are found to consist almost entirely of mucus or of blood and mucus. The mucus is like egg-white, practically odourless, tenacious and sticks to the bed-pan. The blood varies in quantity, and may be seen as mere flecks in otherwise colourless mucus or may be more copious. In more severe cases the mucus becomes yellow and definitely purulent in character. As the case advances towards recovery blood disappears, mucus becomes more scanty, and thicker and brown matter reappears. In mild cases fever and diarrhoea may last only one or two days, while in others it goes on for a week or more. If pyrexia or diarrhoea with mucus persist more than a fortnight, sigmoidoscopic examination should be made.

Shiga Type.—(1) Fulminating cases of Shiga dysentery are occasionally encountered. The onset is sudden, with vomiting and severe watery diarrhoea. The patient rapidly becomes collapsed and dehydrated, muscular cramps ensue, and death with subnormal temperature may supervene in 24 to 36 hours. In these cases the terminal portion of the ileum is frequently involved. As mucus secretion from the necrosed colonic mucosa is impossible, the typical mucoanguineous stools of dysentery never appear. The presence of copious fluid stools may suggest cholera or food poisoning, and in such cases the correct diagnosis may only be made at autopsy.

(2) In severe Shiga infections the onset may be sudden or insidious. In the former case the illness commences with a rigor or feeling of chilliness, associated with fever, headache, nausea or vomiting, colicky abdominal pain and frequent urgent bowel actions. Tenesmus commonly follows. At first the stools are fluid in consistency, brown in colour and contain only flecks of mucus or blood, but soon they become mucoid or muco-purulent in character, and often contain blood and occasionally greenish sloughs of mucous membrane. The presence of considerable quantities of blood or of greenish sloughs in the stool should always suggest a Shiga infection. As the condition progresses the bowels may act twenty to sixty times daily.

In cases with an insidious onset, severe intestinal symptoms and fever may not supervene for several days, during which period the patient may not feel ill enough to go to bed. As the infection progresses and more mucosa is destroyed, bowel symptoms increase and toxæmia appears. The cheeks then become flushed, the eyes bright, the expression anxious, fever increases,

the pulse is more rapid, and the tongue coated and yellow. Restlessness, sleeplessness and delirium develop. When fluid loss continues without compensation, dehydration results; there is increasing thirst, a dry brown tongue, muscular cramps, a dry shrivelled skin, collapsed peripheral veins, a feeble rapid pulse, a low blood pressure, oliguria and an increase in nervous symptoms. Occasionally renal failure complicates the picture. There is albuminuria, granular casts and nitrogenous retention. Oliguria, abdominal distention and hiccough are characteristic. In the most severe cases, anuria supervenes and the patient dies in uræmic coma. Another complication is peripheral circulatory failure associated with decreased blood volume which arises from a combination of toxæmia, dehydration and possibly hypoproteinæmia consequent on the loss of serum protein through the extensively ulcerated colonic mucosa; it is generally fatal.

Sometimes infection of the colon extends more deeply, involving the muscular coat and even the peritoneum, which becomes inflamed; subacute or chronic peritonitis with serous effusion results. Under these circumstances the abdomen becomes distended, the abdominal muscles tender and somewhat rigid, and there may be dullness in the flanks or free fluid demonstrable. Flatulence, vomiting and colicky abdominal pain prove troublesome. A polymorphonuclear leucocytosis is characteristic. The condition is non-surgical, and must be differentiated from acute peritonitis secondary to perforation which demands immediate laparotomy.

(3) The less severe Shiga infections present much the same picture as the Flexner-Boyd group already described. They cannot be differentiated clinically and can only be diagnosed by bacteriological methods.

Sonne Type.—This type particularly affects children, but may also occur in epidemic form in adults. The clinical picture is frequently mild, resembling that described in the Flexner-Boyd group.

SUBACUTE DYSENTERY

In the subacute stages of dysentery, looseness of the bowels and the passage of stools showing mucus and traces of blood persist. Fever may or may not be present.

Sigmoidoscopy generally reveals ulcerative lesions which may or may not be associated with generalised inflammation of the mucosa. The ulcers seen may be (1) small superficial and clear cut and well-defined edges; (2) like aphthæ with yellowish-white exudate; (3) punched-out in appearance, with vertical walls and covered with muco-pus; or (4) small discrete nodular-like lesions with a yellow crust, and on scraping a bleeding crater is left containing exudate of bacillary type from which *B. dysenteriæ* can be cultured. Patients with these small local ulcers and normal intervening mucosa may have periods of complete remission of symptoms, interspersed with mild attacks of looseness of the bowel, and the passage of stools containing mucus and possibly blood. A proportion of carriers belong to this category, and it is probable that every carrier has some local ulcer or area of inflamed mucosa somewhere in the large bowel serving as a source of *B. dysenteriæ*. Such lesions, however may not be demonstrable in the limited area of the colon examined during sigmoidoscopy.

CHRONIC DYSENTERY

Two types may be encountered.

(1) The patient gives a history of dysentery from which he has failed to recover. Looseness of the bowels follows, the stools containing mucus, muco-pus and sometimes blood. In such cases the bowels may have acted 5 or 6 times every day for 6 months or longer. Sigmoidoscopy reveals normal mucous membrane except for numerous circular or oval ulcers up to 1 cm. in diameter. Microscopic examination of the muco-pus obtained during this examination shows bacillary exudate, and culture is positive for *B. dysenteriae*, especially of Shiga variety.

(2) The patient gives a similar history, but is more ill, and during exacerbations fever may recur. Evidence of malnutrition is more marked; the loss of weight is greater and such patients tend to become miserable and emaciated. Secondary anaemia and oedema of the legs may develop. The abdomen is scaphoid, and the thickened colon is readily palpable during physical examination. Sigmoidoscopy reveals that the large bowel is tubular in outline, the walls thickened and contracted, and difficult to distend. The surface is composed of red granulation tissue, which bleeds readily on instrumentation. The general appearance resembles that seen in ulcerative colitis, and in severe cases the patulous condition of the anus, the atrophied appearance of the perianal skin, and the wasting of the gluteal and perineal muscles are common to both diseases. The radiological picture also shows a smooth tubular bowel with loss of haustration. In chronic dysentery of this type the inflammatory process extends deeply, involving the muscular coats leading to thickening, fibrosis and loss of function. Culture of muco-pus obtained at sigmoidoscopy may reveal *B. dysenteriae*, and so differentiate the condition from ulcerative colitis.

Complications and Sequelæ.—Complications in both Flexner-Boyd and Shiga types of dysentery are infrequent, and are mainly encountered in the severe infections. Intestinal complications include hæmorrhage, which may be severe, especially in Shiga infection, perforation with peritonitis, chronic peritonitis with localised or general effusion of peritoneal fluid, hæmorrhoids, rectal prolapse, and painful excoriation of the anus. Peripheral circulatory failure and renal failure are not uncommon complications in severe Shiga infections, and have been already described. Peripheral neuritis, toxic arthritis, conjunctivitis, iritis, pneumonia, parotitis, petechial and purpuric skin rashes occasionally occur. Toxic arthritis is found in both Flexner and Shiga dysentery. It takes the form of effusion into joints and peri-arthritis, and generally comes on from the third to fifth week, or during convalescence. The large joints are prone to be attacked. It often persists for many weeks, but recovery without permanent deformity follows.

Diagnosis.—Many cases regarded as simple diarrhoea are caused by *B. dysenteriae*. In bacillary dysentery the attack is almost invariably heralded by colicky abdominal pain, followed by urgent diarrhoea. Fever is generally present at the first examination, which may reveal localised abdominal tenderness in the course of the colon. The stools may be liquid in consistency and brown in colour at onset, but even at this early stage careful examination will generally reveal flakes of mucus containing exudate of bacillary type.

In a typical case the stools show clear glassy mucus, with or without bright red blood, and later muco-pus. Any case suddenly developing colicky abdominal pain, urgent diarrhoea with flakes of mucus or naked-eye mucus with or without blood in the stools and fever should be regarded as bacillary dysentery until proved otherwise. When feasible this tentative diagnosis should be confirmed by laboratory investigation and, if necessary, by sigmoidoscopy. Typical bacillary exudate is composed predominantly of polymorphonuclear leucocytes, with or without macrophages, epithelial cells and red blood corpuscles. Stools sent for culture should contain mucoid exudate, be absolutely fresh, and uncontaminated by urine or antiseptics. *B. dysenteriae* may be isolated at any stage of the disease, especially if desoxycholate-citrate agar media be used and material for culture be obtained during proctoscopy or sigmoidoscopy or by rectal swab.

Sigmoidoscopy.—This can be carried out for diagnostic purposes early in the disease, but at this stage is generally not necessary. When the symptoms persist for more than 10 days the information obtained is valuable in prognosis, as the healing or extension of the lesions can be followed. From a diagnostic viewpoint not only do the appearances of the bowel wall indicate the nature of the disease, but by swabbing the ulcers ideal material can be obtained for culture and determining the type of exudate, while gentle curettage of the ulcer surface will supply material enabling vegetative forms of *E. histolytica* to be demonstrated if amoebiasis be present. In bilharzial dysentery papillomata or other lesions may be found; microscopic examination of material obtained from scrapings will reveal numerous ova. In the differentiation of the chronic dysenteries sigmoidoscopy is indispensable.

Bacterial food poisoning with organisms of the Salmonella group may need differentiation. The sudden and simultaneous onset of severe gastrointestinal symptoms, with prostration, in a group of people who have consumed the same meat, milk or other food within 6 to 36 hours previously is suggestive. Culture of *B. aertrycke* or *B. enteritidis* Gaertner will confirm the diagnosis, though it is not always possible to isolate the responsible organism. Blood and mucus is rarely present in the stools in Salmonella infections.

Course and Prognosis.—Most non-Shiga dysentery infections run a benign course, and many cases of catarrhal type are so mild that they clear up in a few days without specific treatment; in others, fever and intestinal symptoms persist for 1 to 3 weeks before subsiding; and in a minority, subacute or chronic dysentery may result. Fatal cases are generally of Shiga type, death occurring in from 30 hours to 3 months of onset. In some epidemics, especially amongst Japanese and debilitated natives, the mortality rate has been 25 to 50 per cent. In infants and young children, the aged and people who are malnourished or suffer from intercurrent disease, *B. dysenteriae* of Flexner, Schmitz and Sonne types may cause death. The mortality rate in British Forces in Egypt, Macedonia and Mesopotamia during the last world war was 27 per 1000. In Australian troops in New Guinea in the present war it has not exceeded 0.2 per 1000, a result attributable to the lower incidence of Shiga infections and the efficacy of early sulphaguanidine therapy. (See also Specific Chemotherapy, p. 124).

Treatment.—*PROPHYLACTIC.*—As dysentery is spread by water or food contaminated either directly from a patient or human carrier or indirectly by flies, measures similar to those adopted for enteric fever and cholera are

indicated. No satisfactory prophylactic vaccine is available. Sulpha drugs, by limiting the number of stools and rendering them non-infective, constitute a potent means of controlling epidemics, and by curing the patient they prevent the development of carriers.

CURATIVE.—Rest in bed and good nursing are essential. Special attention should be directed to the correct dosage of the particular sulpha drugs administered, maintenance of a positive fluid balance to prevent dehydration, regular feeding, the hygiene of the mouth, and the prevention of bed-sores.

Dietary.—In all cases for the first 24 hours only water is allowed, to which may be added glucose, lactose, or cane sugar. Subsequently, albumen or barley water, tea and chicken broth are given; followed by soups, marmite, orange juice, jelly, biscuits, dry toast, clear honey, whey, sprulae and apple purée. Later, arrowroot, cornflour, ground rice, sago puddings, and, as improvement continues, by eggs, non-fatty fish, chicken, butter, milk drinks, junket and stewed fruit may be taken. Adherence to this type of low residue diet is necessary in severe cases, especially Shiga infections, in order to rest the bowel; but in dysentery of ordinary severity and of non-Shiga type, milk drinks, milk puddings, toast and cereals may be introduced as first additions to the initial diet of clear fluids and jellies once the stools have been reduced to 6 to 10 per day; and proteins are allowed shortly afterwards.

Specific Chemotherapy.—Various sulphonamides, including sulphaguanidine, sulphasuxidine, sulphapyridine, sulphathiazole and sulphadiazine, have been shown to exert specific curative effects in bacillary dysentery. Owing to its poorer absorption, lower toxicity and absence of renal complications, sulphaguanidine (p-amino-N guanylbenezene sulphonamide) has special advantages over most of the other sulphonamides for use in hot climates in dehydrating intestinal diseases like Shiga dysentery and cholera which may be complicated by renal failure and anuria. Crystals of acetyl-sulphaguanidine do appear in the urine, but they are deposited as a soft mush and not in the form of hard renal concretions, as in the case of most other sulphonamides. Once a tentative diagnosis has been made on clinical grounds, specimens of the stool should be obtained and forwarded to the laboratory for a report on the microscopic and cultural findings. Treatment, however, should not be delayed pending the laboratory report for by so doing valuable time is lost.

Sulphaguanidine is given in an initial dose of 0.1 g. per kilo body weight, followed by a maintenance dose of 0.05 g. per kg. 4-hourly for the period during which the number of stools passed exceeds 5 per day, and subsequently a dose of 0.05 g. per kg. every 8 hours until the stools have been normal in number and consistency for 2 days. The duration of treatment should not exceed 14 days, but if necessary the course can be repeated after the lapse of a week. Thus, a patient weighing 11 stone would receive 7.0 g. as an initial dose, 3.5 g. 4-hourly, and later the same dosage 8-hourly. With Shiga dysentery, if the patient is not treated until the third day or later, it is not uncommon for 150 to 200 g. to be administered over a period of 8 to 12 days.

The response of acute dysentery to sulphaguanidine therapy is remarkable. If the drug be given within a few hours of onset, the attack of dysentery is generally aborted; fever disappears, the diarrhoea and abdominal pain cease in 24 hours, and the stools soon become normal. In Shiga cases when

treatment is delayed 2 or 3 days or longer, inflammation and destruction of mucous membrane have already resulted. Despite this, the response is generally striking. There is an early feeling of well-being, rapid relief of abdominal pain and a decrease of abdominal symptoms. In uncomplicated cases an early reduction of the temperature and pulse is noted, the normal being reached in most cases in 1 to 3 days. There is also a remarkable reduction in the number of stools, and blood disappears rapidly from the faeces and mucus a few days later. When the treatment of Shiga dysentery commences from the third day to the third week of the disease, normal bowel action can be expected in about 5 to 6 days, and formed stools in about 8 days.

In subacute and chronic cases, in which the bowels are acting some 3 to 8 times daily, the treatment consists of 0.05 to 0.1 g. per kg. every 8 hours for 7 days. Should this not be effective it will be necessary to repeat the course later or to substitute one of the other sulphonamides for sulphaguanidine.

Full dosage and a complete course of treatment as prescribed for chronic dysentery is the most effective means of eliminating carriers of *B. dysenteriae*.

If colicky pain or tenesmus are severe during the first 24 hours, morphia grs. $\frac{1}{4}$ may be given and repeated next day, but this is rarely necessary. Heat in the form of antiphlogistine or turpentine stupes applied to the abdomen may also be helpful before sulphaguanidine has exerted its maximal beneficial effects. Dehydration should be prevented by administering as much fluid *per os* as can be comfortably taken. The fluid intake should be sufficient to ensure the secretion of 2 pints of urine daily. When there is severe vomiting or copious fluid stools, intravenous injections of saline (0.85 per cent.) and glucose (5.0 per cent.) solution are administered either intermittently or by continuous drip. In the terminal phase, when there is peripheral circulatory failure, liquid serum or reconstituted plasma may be added. Blood transfusion is advisable if the patient is markedly anæmic or intestinal hæmorrhage is severe.

Sulphasuxidine (succinyl-sulphathiazole) is another sulphonamide which is being used successfully in the treatment of dysentery, and is said to be more effective than sulphaguanidine in the treatment of Sonne dysentery and in the eradication of *B. dysenteriae* Sonne in carriers. It is poorly absorbed, not more than 5 per cent. being excreted by the kidneys. Like sulphaguanidine, the dosage is considerable, being 0.25 g. per kg. initially and 0.04 g. per kg. 4-hourly thereafter.

Sulphadiazine, in a dosage of 4 grammes daily, is widely advocated in U.S.A. It has the advantage that a smaller dosage of the drug is required, but it is not suitable for use in dehydrated patients in the tropics until the fluid balance has been restored.

Specific Anti-Dysenteric Sera.—Now that specific drugs are available there is little need for immunological therapeutic reagents.

Refined monovalent anti-dysenteric Shiga serum has a limited field of usefulness in (a) fulminating Shiga infections to control circulating exotoxin while the sulphonamide is exerting its local bacteriostatic action on *B. dysenteriae*, (b) those rare Shiga infections which are not showing a satisfactory response to sulphonamide therapy. The daily dosage should not be less than 200,000 I.U. administered intravenously; in fulminating cases 200,000 I.U. may be repeated every 4 to 6 hours. This anti-serum possesses

the advantages of rarely, if ever, causing serum sickness or other adverse reactions. Its disadvantage lies in the fact that it is purely anti-toxic and possesses no bacteriostatic or bacteriolytic action on *B. dysenteriae* Shiga; for this reason its beneficial effects are only temporary. Polyvalent and multivalent anti-dysenteric sera frequently give rise to serum reactions, and are of very doubtful therapeutic value. No satisfactory anti-sera have yet been produced for the Flexner-Boyd group. Bacteriophage therapy has also proved disappointing. Boyd has recently demonstrated that strains of *B. dysenteriae* may persist along with their specific bacteriophages in the stools of uncured dysentery patients.

Sodium or Magnesium Sulphate.—This was the standard treatment for dysentery before the introduction of specific sulphur drugs. It is now only used if these specific drugs are not available. The initial dose is 2 drachms; subsequently 1 drachm is given 2-hourly for the first 12 to 24 hours, and then 4-hourly, 6-hourly and finally 8-hourly for the next 3 or 4 days or until the stools become faeculent. It is inadvisable to continue sulphate therapy longer than 4 or 5 days, as in many cases it merely keeps up the diarrhoea.

Treatment of complications.—Intestinal hæmorrhage is best treated by sulphaguanidine, morphia injections and blood transfusions. Surgical intervention is rarely justified. Perforation of the bowel calls for immediate laparotomy; the prognosis is very grave for the bowel wall is generally necrosed. Joint complications do not generally respond to specific therapy and require treatment along general lines.

CHOLERA

Definition.—A specific disease due to Koch's comma vibrio, characterised clinically by violent vomiting, painless diarrhoea with copious rice-water stools, dehydration, muscular cramps, aphonia, collapse, and urinary suppression.

Ætiology.—Cholera exists endemically in India, China and certain other Far Eastern countries. In India Rogers demonstrated three main endemic foci from which epidemics spread in the spring and summer through mass movements of pilgrims who acquired the disease from infected water. War may lead to the spread of cholera, and herding of people in famine and prison camps also favours outbreaks. Occasionally cholera has reached Europe. People of different race, sex and age are all susceptible.

The causative organism is *Vibrio cholerae*, described by Koch (1883). The true cholera vibrio (1) ferments mannose and sucrose but not arabinose, (2) does not hæmolyse goat's erythrocytes, and (3) agglutinates with O-group 1 serum. The status of the hæmolytic El Tor and Celebes strains of vibrio remains undecided. Water transmission is an important mode of spread. When the general water supply becomes infected, as in the Hamburg epidemic (1892), a sudden widespread outbreak follows. If wells or other local water supplies are infected, cases appear from day to day in the locality so supplied. Flies also may disseminate the disease by contaminating food, milk, etc., with infected feces. Cholera vibrios occur in great numbers in the rice-water stools, but disappear rapidly. Both the cholera convalescent and the contact carrier lose their vibrios within a few days of the termination of the attack or

contact with a cholera case. Chronic carriers, as in typhoid fever, are unknown, and the actual cholera patient remains the main source of spread. Choleraphage is said to be absent from the stools of the most virulent cases, and present in mild and convalescent ones. It is also claimed that bacteriophage may convert virulent, highly agglutinable vibrios into non-agglutinable ones.

Pathology.—After death rigor mortis sets in early. The blood is thick and tarry. The small intestines are collapsed and shrunken, the mucosa is denuded of its epithelial lining, congested, and perhaps hæmorrhagic, and the lymphoid follicles are enlarged. The stomach and liver are congested, and the gall-bladder distended with viscid thick bile, difficult to expel—hence absence of bile in the intestine. The kidneys show swelling, congestion and ecchymoses, the spleen is small and shrunken, and the lungs collapsed and dry.

The cholera vibrio is readily isolated from the contents of the small intestine and occasionally from the gall-bladder. The vibrios undergo disintegration on the surface epithelium, especially of Lieberkühn's glands, with liberation of a powerful endotoxin. Denudation of intestinal epithelium, outpouring of fluid from the blood vessels into the lumen of the bowel, and absorption of toxin into the circulation result. Toxæmia and fluid loss underlie the pathological findings and clinical picture. Diarrhœa and vomiting lead to chloride depletion, to decrease in blood volume with increased viscosity of the blood, and to tissue dehydration. Biochemical investigations show reduced blood chloride, diminished plasma alkalinity, phosphate retention, and increased blood urea. A polycythæmia of six to eight million red corpuscles per c.mm. and a leucocytosis of from 15,000–30,000 per c.mm. are frequently found; hæmatocrit estimations have shown an average loss in serum of 35 per cent. in mild and up to 64 per cent. in severe cases. Finally, the weakened heart may prove incapable of pumping the viscid blood through the damaged kidneys and anuria may result. Decreased filtration pressure is an important factor in the failure of renal secretion.

Symptoms.—The incubation period is two to five days.

Five clinical types have been described. (1) *Ambulatory cases*. (2) *Choleraic diarrhœa*. (3) *Cholerine*: the patient suddenly develops severe abdominal pains, passes numerous fæculent motions, then typical rice-water stools, followed by rapid recovery. (4) *Cholera sicca*: the patient becomes rapidly collapsed and dies before the typical gastro-intestinal features develop. (5) *Cholera gravis*: typical cholera, constituting 95 per cent. of the cases in most epidemics. Premonitory symptoms are frequently absent but occasionally there may be looseness of the bowels, headache, epigastric discomfort, nausea and possibly vomiting some 24 hours before true choleraic diarrhœa develops. In the ordinary severe cases three stages may be recognised.

1. **Stage of evacuation.** This lasts 3 to 12 hours. The onset is generally abrupt, with painless diarrhœa and vomiting. Soon the stools lose their fæculent character, purging becomes marked, and the evacuations are frequent and copious; the stools now resemble rice-water and contain flakes of epithelium. Colicky pain is absent; evacuation of the bowels brings relief, but this is soon followed by a sense of prostration. Vomiting commences early: at first the stomach contents are ejected; later, several quarts of rice-water vomitus may be lost in a few hours. Severe retching is common,

and hiccough may be troublesome. As a result of sodium chloride loss, agonising cramps now appear, often commencing in the hands and feet and extending to the extremities or abdominal muscles. The patient also suffers from intense thirst, and becomes restless and exhausted. The skin is cold and wrinkled, the lips and lobes of the ears bluish, the face appears pinched, the conjunctivæ are injected, the eyeballs sunken, and the voice husky and weak. Aphonia often supervenes. The respirations become rapid, the blood pressure lowered, the peripheral veins depleted and collapsed, and the pulse almost imperceptible. Though the skin temperature is subnormal, in the rectum it may reach 101° to 104° F.

2. Algid or collapse stage. In this stage the vomiting and purging lessen or cease, but symptoms of collapse increase. Circulatory failure follows. Despite this, the mind generally remains clear. The cholera facies becomes even more accentuated, the skin cold, clammy and dusky, and cyanosis is marked. The pulse, which is irregular and weak, may disappear completely at the wrist. The systolic blood pressure may fall to 40–70 mm. Cardiac sounds are weak, and a friction rub, caused by dryness of the scrous surfaces, may be heard over the pericardium and pleura. Urinary secretion is markedly decreased as a result of hypotension and dehydration, and the scanty urine contains albumin and casts. Unless the low blood pressure be maintained, oliguria may be replaced by anuria. Death may occur within 3 to 48 hours of the onset of these symptoms; peripheral circulatory failure and uræmia are the most frequent causes. About 50 per cent. survive this stage of collapse, and pass on to the stage of reaction.

3. Stage of reaction. With recovery, the temperature rises, the circulation and blood pressure improve, cyanosis decreases, the urinary secretion increases, and the stools become fæulent and contain traces of bile. Recovery may ensue within a week. In less favourable cases, especially when the collapse stage has been prolonged, a typhoid state may develop. The face is flushed, the temperature rises, the pulse and respirations are accelerated, and the tongue is dry and brown; and erythematous rashes may appear and low muttering delirium ensues. The blood pressure in these cases may be elevated above normal (150–175 mm.). The cause of the syndrome is believed to be absorption of cholera or other bacterial toxin from the damaged bowel after the circulation has been restored. Fatal cases may die with hyperpyrexia. In other cases, despite circulatory recovery, urinary secretion is not re-established, no urine or only a small quantity of albuminous urine being passed. Increased respirations, Cheyne-Stokes breathing, hiccough, twitching muscles, stupor, delirium, convulsions, and coma follow. Death is due to renal acidosis and uræmia.

Polyerthæmia and leucocytosis have been noted under Pathology.

Complications and Sequelæ.—Cardio-vascular collapse, renal acidosis and uræmia, and toxæmia producing a typhoidal state are common modes of death. Despite the frequency of uræmia, chronic nephritis rarely follows cholera. Complications also include broncho-pneumonia, cholecystitis, parotitis, and bed sores; and gangrene of the fingers, toes, ears, penis and scrotum have been recorded. Lack of lacrimal secretion may lead to conjunctivitis, corneal ulceration and sloughing of the cornea. Miscarriage and premature delivery are not infrequently caused by toxæmia, severe purging, and cramps in the abdominal muscles.

Diagnosis.—When cholera is prevalent the only safe rule is to treat every case of diarrhoea as suspect until proved otherwise. Laboratory confirmation in all atypical cases should be sought.

During an epidemic little difficulty will arise, but in atypical and sporadic cases the diagnosis will largely be made on a positive stool culture. Outbreaks of food poisoning (*Cholera nostras*) due to organisms of the salmonella group may be differentiated by the history, the presence of bile in the stools, and laboratory investigation. In mushroom poisoning the history is important and particles of the fungus may be identified in the vomitus or stools. Malaria, dysentery, early trichinosis and infection with *Gastrodiscus hominis* may occasionally produce acute gastro-intestinal features somewhat resembling cholera; laboratory investigations will clinch the diagnosis. In poisoning by arsenic or mercury perchloride, vomiting generally predominates, the stools contain bile and sometimes blood, and there may be a marked metallic taste in the mouth.

Prognosis.—The mortality rate has varied in different epidemics from 30 to 80 per cent., being most fatal at the start. Modern treatment has reduced it to about 20 per cent. Over 90 per cent. of cases admitted with a blood pressure above 70 mm. recover. Young children, pregnant women, aged and debilitated people, alcoholics and chronic nephritics do badly. A severe and prolonged collapse stage, early anuria with uræmic symptoms and hyperpyrexia are unfavourable, but with modern treatment these can often be avoided. (See also Cholera Vaccination below.)

Treatment.—**PROPHYLACTIC.**—Personal prophylaxis is vital. Since cholera vibrios originate in the first instance from patients with cholera, isolation of the patient in fly-proofed wards, destruction of vomitus and excreta, and sterilisation of soiled linen and clothing are most important measures. Water should be sterilised by boiling or chlorination, and water and food adequately protected against pollution or contamination by flies. Cold meat, shell fish, salads, and raw fruit should be avoided, and the hands invariably well washed in antiseptic solution before eating. Drinking vessels and eating utensils should be cleaned in boiling water and dried by heat. Scrupulous care of the ice chest is essential. Houses should be fly-proofed where possible.

Cholera vaccination produces some degree of temporary immunity any is valuable in epidemics, provided virulent strains of vibrios have been used in the manufacture of the vaccine. The vaccine contains 8000 million vibrios per c.c.; the first dose is $\frac{1}{2}$ c.c., followed in ten days' time by 1.0 c.c. An "booster" dose of 1.0 c.c. should be given at least every six months if continued protection be desired. In India, vaccines containing Inaba and Ogawa strains have yielded promising results. Immunity develops rapidly in from four to ten days, and probably lasts four to six months. The mortality rate in the vaccinated remains high, but is reported to be about two-thirds that of the uninoculated. The value of cholera phage as a causal prophylactic during an epidemic is undetermined, while its practical value in eliminating cholera vibrios from wells and cisterns is also uncertain.

CURATIVE.—Specific treatment resulting in the destruction of cholera vibrios and toxin remains a therapeutic ideal yet to be achieved. Intestinal antiseptics have failed. The ordinary sulphonamides do not appear to have been successful. Sulphaguanidine and succinyl-sulphathiazole await adequate

trial, but certain recent reports indicate that sulphaguanidine may exert specific therapeutic effects similar to those in bacillary dysentery. It should be given as early as possible and in conjunction with, not in lieu of, intravenous fluid therapy. A dosage similar to that adopted in bacillary dysentery would appear appropriate, and the dose should be repeated if vomited. No unanimity of opinion exists in regard to bacteriophage, which is administered orally at short intervals in a dose of 4 c.c. As much as 100 c.c. has been given on the first day, and 50 c.c. within the next 24 to 48 hours.

Apart from specific therapy, intravenous fluid medication and other measures have lowered the mortality from approximately 60 per cent. to 20 per cent. The principles involved are designed to: (1) rest the small intestine; (2) replace fluid, salts and serum protein lost from the blood; and (3) restore the acid-base equilibrium of the blood and tissue fluids. By so doing circulatory failure, hypochloræmia, renal acidosis, and uræmia are prevented or combated.

The patient is kept strictly in bed, and only water and rice or barley water are given by the mouth for the first few days. Frequent drinks, not exceeding 2 ounces, should be administered. During the collapse stage efforts should be made to conserve the body heat; hot-water bottles are useful for this purpose. Morphia is only used in the stage of premonitory symptoms; it is contraindicated later. Intravenous medication is all-important, solutions of isotonic or hypertonic saline with or without sodium bicarbonate and plasma being largely employed. Various indices have been used to estimate the amount of fluid required to be injected in the individual case. These include: (1) the specific gravity of the blood; (2) the blood pressure and pulse; and (3) the hæmoglobin concentration. Rogers advocates two solutions: (a) Hypertonic saline (sodium chloride 120 grs.), calcium chloride 4 grs., water 1 pint) for reinforcing blood volume and chloride loss; and (b) an alkaline solution (sodium bicarbonate 180 grs., sodium chloride 90 grs., water 1 pint) to counteract acidosis and uræmia. During the *collapse stage* 1 pint of (b) is first given, and then the total quantity as estimated from the specific gravity of the blood is made up with Rogers' hypertonic saline solution (a). Thus a specific gravity of 1063-1064 calls for 3 pints, and between 1065-1070 for 4 to 6 pints, the aim being to keep the figure below 1060. Injections are repeated as often as the specific gravity of the blood rises to or above 1063, or the blood pressure falls to 70 mm. Other solutions in use consist of isotonic saline, 5 per cent. dextrose, and a combined sodium chloride (1.4 per cent.) and sodium bicarbonate (0.5 to 3.0 per cent.) solution. The latter should be sterilised, either by filtration or by adding the sodium bicarbonate to the cooling salt solution after it has been sterilised by heat. It is not permissible to boil or autoclave sodium bicarbonate, as it is converted into the toxic carbonate. Another satisfactory method of rapid alkalization of the urine consists of the repeated intravenous injection of sodium-lactate (4 molar) and saturated sodium bicarbonate, as advocated in black-water fever.

Owing to serum protein lost through the intestine, plasma in a dosage of 250 c.c. may be given in addition to the above-mentioned solutions, and repeated as required.

Fluid should be administered intravenously, either intermittently or by continuous drip. If for any reason fluids cannot be injected into the veins they can be introduced intrasternally or subcutaneously.

The pulse and blood pressure probably serve as the best indicator of blood fluid requirements. A blood pressure below 70 mm., especially if there is associated cyanosis, restlessness, cramps and cold extremities, necessitates immediate transfusion. The result is dramatic, provided an adequate quantity of fluid be injected. Profound collapse is relieved, the skin becomes warmer, cyanosis disappears, and the pulse and blood pressure are markedly improved. Injections should not be continued after the pulse and blood pressure have been restored. Cases of moderate severity were found by Sellards to require 2 litres of fluid every six or eight hours for one to two days. As much as 31 pints in four days have been given in a severe case with resultant recovery. Special care should be taken (1) to avoid pyrogens in the water used for intravenous injection, (2) to see that the temperature of the injected fluid does not exceed 80° F. (room temperature in the tropics), if the rectal temperature be elevated. The former precaution is necessary to prevent rigors, and the latter to prevent hyperpyrexia.

In the reaction stage, cold sponging is advisable whenever the temperature exceeds 103° F. Threatened uræmia is treated by alkaline drinks, injection of alkaline saline solutions per rectum and intravenously, and dry cupping. Hot packs should not be used. Throughout this stage constant care is necessary, the chief dangers being hyperpyrexia and renal failure. In the treatment of hyperpyrexia, cold sponging, an ice cap to the head and cold saline enemata may be tried; if these fail the patient should be placed on a rush mattress, and covered by a sheet over which water is sprinkled and on which a fan plays to cause evaporation. When the blood pressure fails to rise, repeated adrenalin injections are said to be helpful.

As long as the renal function is depressed no increase in the diet should be made, and even after all acute symptoms have subsided the patient should be nursed in bed in the recumbent position for several days, as fatal syncope may ensue if he sits up prematurely. When patients can tolerate food, the diet should at first be low in residue. Broths, jellies, white of eggs, underdone minced meat and farinaceous foods reinforced by vitamins are permitted.

LEPROSY

Definition.—Leprosy is a chronic bacillary disease of low infectivity peculiar to man, caused by the *Mycobacterium lepræ*, and associated with characteristic lesions involving the skin and mucous membranes (nodular type), and the nerves (anæsthetic type). Infection, however, may remain latent and clinical manifestations never appear.

Ætiology.—The disease has a widespread geographical distribution, occurring in Egypt, Asia, Africa, West Indies and the Pacific Islands, etc. It is not hereditary, and individuals of any age, sex and race may be attacked. Children are more susceptible than adults. The *Mycobacterium lepræ* was discovered by Hansen in 1874; it is a non-motile, acid-fast bacillus occurring in large clumps in skin lepromata, septal ulcers and nasal mucus, and has never been cultivated with certainty. The mode of spread is unknown, but intimate contact with lepers is essential; a history of attendance on lepers, of living in the same house, sleeping in the same bed, or sexual connection is frequently obtained. Only 3 per cent. of people, however, living in the same household as a leper develop the disease. *Helminthica*. The

Pathology.—Leprosy bacilli spread through the lymphatics of the corium and subcutaneous tissues, producing granulomata of the skin and infection of lymph glands; the nasal and buccal mucous membrane, the eye, larynx and internal organs, such as the liver, lungs and testicles, may be similarly involved and bacilli found. The nerves may swell, turn a reddish-grey colour, and undergo an axonal degeneration; scanty bacilli may be demonstrated in the endo- and perineurium. Paralysis, muscular atrophy and deformity follow.

Symptoms.—There are three main types of the disease—(1) nodular or cutaneous leprosy; (2) anæsthetic, neural or nerve leprosy; (3) mixed leprosy. The incubation period is uncertain, being one to five years in most cases, though occasionally persons develop it a few months after coming into an infected area. Often bacilli remain latent for years, and intercurrent disease may be necessary to precipitate clinical leprosy.

1. NODULAR OR CUTANEOUS LEPROSY.—This is the low resistant type, in which there is gross infection of both skin and nerves; the neural signs are mild, since the invading organisms fail to elicit any marked response from nerve tissue (Muir). Prodromata, which are marked, include leprotic fever, rigors, sweating, progressive weakness, diarrhoea, alternating dryness and hypersecretion of the nasal mucosa and epistaxis. The first positive evidence is the primary exanthem, involving especially the face, buttocks, legs or arms, commencing as a slightly raised erythematous macule which later shows dissociation of sensation and absence of sweating; it may disappear, leaving some brownish discoloration, but soon fever recurs with a fresh eruption, and bacilli may be found in the blood. After one or two recurrences reddish-brown elastic nodules appear, often at the site of the old macular rash, and these may become more generalised. Only the dorsal surfaces of the hands and feet are affected. The face acquires a leonine aspect from the enlarged nose, lobes of the ear and pendulous cheeks. The hair is often lost, especially on the outer third of the eyebrows, the nipples become prominent, the breasts may hypertrophy, and the mucous membrane of the nose, pharynx and larynx may be affected. Leprotic nodules often involve the cornea and iris. The further history varies; the nodules may remain stationary, disappear or break down and suppurate. Ulcers may form on the eye, causing blindness, and the larynx and pharynx may be destroyed.

2. ANÆSTHETIC LEPROSY.—This is a highly resistant type, in which the infection of skin and nerves is less, yet the neural signs are more prominent since the reaction in nerve tissue is more marked. Prodromata consist of mental depression, chilliness and malaise with neuralgic pains and paresthesias, involving the ulnar, peroneal and facial nerves. Numbness of the hands and feet, anæsthesia of ulnar distribution, and maculæ, giving rise to flat, anæsthetic patches resembling ringworm may be the first indications. These anæsthetic patches may commence as erythematous or pigmented or depigmented areas and ultimately become dry and hairless. A quiescent stage may now set in until definite nerve lesions appear. Demonstrable fusiform enlargement, especially of the ulnar and great auricular nerves may develop, and wasting of the hypothenar eminence associated with the third and fourth fingers is often seen. Muscular palsies of the skin, nails and bones, including perforating ulcers,

are common, and atrophies and contractures like claw hand may ensue. Necrosis or interstitial absorption of the small bones occur, and fingers and toes may disappear. The fifth and seventh cranial nerves are sometimes attacked, and ectropion of the lower lid, followed by corneal ulceration, is common.

3. MIXED LEPROSY.—Many cases ultimately become mixed in type, the nodular and nervous features either developing together or following one another. Tuberculoid leprosy—so called owing to its histological resemblance to tuberculosis—is encountered in patients with a high resistance. The lesions consist of raised plaques or of macules with raised margins : anæsthesia is well marked, and the nerve branch supplying the area is often thickened.

Diagnosis.—Clumps of *lepra bacilli* which have to be distinguished from tubercle can often be demonstrated in nasal mucus, in scrapings obtained from nasal ulcers using a speculum, and in the serous exudate from granulomata of the skin. The “snip method” of removing a small piece of skin with curved scissors, especially from the lobe of the ear, and making smears from its under-surface, is valuable. Gland puncture may also reveal bacilli. In pure nerve cases they can rarely be found unless portions of the nerves be examined. The differential diagnosis includes in nodular leprosy, lupus vulgaris, skin tuberculosis, syphilis and yaws ; and in the anæsthetic type, syringomyelia, Morvan's disease, progressive muscular atrophy, peripheral neuritis, cervical rib, ainhum, scleroderma, and Raynaud's disease.

Prognosis.—This is by no means good in more advanced cases, though with earlier diagnosis and modern treatment the disease may be arrested, the expectancy of life increased and cases sometimes cured. If the patient can tolerate maximal treatment and maintain a sedimentation rate below ten a good prognosis can generally be given. Nodular leprosy is particularly prone to such complications as tuberculosis, renal disease and pneumonia, and laryngeal and visceral involvement are serious.

Treatment.—**PROPHYLACTIC.**—Lepers must be excluded from acting as cooks, waiters, etc., and segregation properly and humanely carried out is best for all parties concerned. Contacts who have lived in the same houses as lepers should be bacteriologically examined every few months for at least five years.

CURATIVE.—As in tuberculosis, the first essential is to increase the general resistance of the patient by good food, fresh air, regulated exercise, and to eradicate intercurrent diseases such as ancylostomiasis, malaria, etc. The confidence and active co-operation of the patient are essential. According to Muir the erythrocyte-sedimentation test affords a valuable index to the patient's resistance, slow sedimentation being favourable. Only when the resistance is high, and the general state of health satisfactory, should special drugs be used with the object of clearing up lepromata, otherwise lepra reactions, with increase in the local lesions, fever and bacillæmia in nodular leprosy and agonising pain in nerve cases, may develop. Too large and too frequent treatments with special drugs are dangerous, the aim being to avoid lepra reactions and to keep the health of the patient at the highest level. Special drugs : the oils of the *Hydnocarpus* and *Chaulmoogra* group have been in use for centuries. *Chaulmoogra* oil (*oleum chaulmoogræ*) is expressed from the fresh ripe seeds of *Hydnocarpus Kurzii* (King N.O. Bixiniæ), that of *Hydnocarpus* from *Hydnocarpus Wightiana* and *H. anthelmintica*. The

crude oil is given by the mouth in 10 minim doses t.i.d., being gradually increased to 60 to 120 mins. per day. Intramuscular injections may be given, but penetration of a vein may lead to a fatal fat embolism. Antileprol, a mixture of the ethyl esters of the various unsaturated acids of chaulmoogra, is given in capsules, each containing 1 gram, the dosage being 1 to 3 grams daily after meals. McDonald and Dean have used weekly intramuscular injections of Moogrol (ethyl chaulmoograte), beginning with 1 c.c. and increasing by 1 c.c. every third injection up to a total of 6 c.c. Alepol (sodium hydnocarpate), 1 to 5 c.c. of a 3 per cent. solution, can be given subcutaneously or intramuscularly without pain; for intravenous injections a 1 per cent. solution is used. Muir advocates the intradermal injection of the skin lesions with sterilised *H. Wightiana* oil, which is heated to 55° C. before use to reduce its viscosity; the injection is made with a short guarded needle inserted at an acute angle for 2 or 3 mm. The dosage varies, according to the tolerance of the patient, from 0.5 to 5.0 c.c. once or twice a week. From 0.03 to 0.06 c.c. is injected at each puncture, and some 80 to 100 punctures are required to inject 5 c.c. Six months may be necessary to infiltrate once all the affected skin, while another disadvantage is the pain it may produce. Hydnocarpus oil injected intradermally is stated to act as a local irritant stimulating phagocytosis and possibly antibody reaction from the absorption of lepromatous material, while protein shock effects may also be so induced. Whatever its action, the dosage must be carefully graded and only given when resistance is high.

Any erythematous or raised appearances of the skin or thickened and tender nerves indicate activity of the disease, and cases should be free from *Myco. lepræ* for at least two years before discharge; even then it is not possible to say whether the condition is really cured or merely arrested, for leprosy is notoriously a disease of remissions.

Leprosy reaction should be treated with diaphoretics such as aspirin, phenacetin, hot drinks, and calcium and alkalis in large doses; small doses of tartar emetic (0.02 to 0.04 gram every second day) and protein shock may be useful. In nerve leprosy the agonising pain may be relieved by adrenaline intramuscularly or ephedrine given orally or by infiltration of the nerve. Vitamin B₁, given by intramuscular injection and by the mouth, in large doses, may lead to a rapid disappearance of neuritic pain, and a diminution in the tenderness and swelling of the nerves.

Potassium iodide is a dangerous drug, but Muir uses it in the late stages of treatment when the resistance is high and the case has become bacteria-free. Diathermy is of value in subacute and chronic nerve lesions. If the ulnar nerve is bound down to bone—especially at the elbow—freeing adhesions and linear incision of the sheath with or without removal of fibrous tissue may bring relief. Abscesses occurring in the ulnar or other nerves should be incised; drainage is rarely needed.

MELIOIDOSIS

Definition.—A fatal ³⁴disease, resembling glanders in symptoms and pathology, caused by *Bacillus whittmori*; it has been found in Burma, British Malaya, Cochin China and Ceylon, and is primarily a disease of rodents; the mode of human infection is unknown.

Pathology.—The characteristic lesions are small caseous nodules which sometimes coalesce, forming large honeycombed abscesses in the viscera. The lungs, liver, spleen and, less commonly, the intestines and kidneys may be implicated, while pustules and bullæ may involve the skin. *B. whitmori* is readily cultivated from these lesions as well as from the blood during the septicæmic stage, but the safety-pin-like bipolar staining organisms are scanty in smears of the pus obtained from the nodules.

Symptoms.—In severe cases the vomiting, purging and collapse may simulate cholera, and death from septicæmia may occur in three days; other cases may show remittent and intermittent pyrexia for weeks and months. The clinical picture varies with the organ predominantly attacked, and according to Stanton and Fletcher the clinical types may resemble: (1) plague; (2) broncho-pneumonia; (3) typhoid or malaria; (4) liver abscess; (5) infective endocarditis or general tuberculosis; (6) pyelitis.

Diagnosis.—This is always difficult clinically, and is dependent on the cultivation of the organisms from the blood, sputum, urine, cerebro-spinal fluid or material aspirated from the liver or spleen. Only 10 per cent. of cases have been diagnosed during life.

Treatment.—Food should be protected from contamination by rats and other rodents. In man the disease is almost invariably fatal, only two cases having recovered. Autogenous vaccines are worth a trial, but neither vaccines nor anti-sera possess protective power in infected animals.

PLAGUE

Synonyms.—Oriental Plague; Pest; Black Death.

Definition.—Plague is primarily a disease of rodents caused by the *Pasteurella pestis*. Transmitted to man by rat fleas, it runs a rapid course with high fever, and a marked tendency to septicæmia and tender enlargement of lymphatic glands. More rarely a pneumonic form develops.

Ætiology.—Plague may occur anywhere; it is more common in sub-tropical regions, but towards the equator tends to die out. High temperatures and a dry atmosphere or high saturation deficiency reduce its incidence in the hot weather in India by killing the flea vector. It spread from Hong-Kong to India, Egypt and Japan in 1896, and three years later to the Philippines and South America. People of any race, age or sex are susceptible. The plague bacillus, *Pasteurella pestis*, was isolated by Kitasato and Yersin in 1894. It is readily cultured, and is a short, Gram-negative rod showing bipolar staining. Guinea-pigs and other laboratory animals are susceptible. Rat fleas, especially *Xenopsylla cheopis*, which have fed on the blood of infected rodents such as the large grey rat (*Rattus norvegicus*) and the smaller black rat (*Rattus rattus*), desert these animals after death and inoculate man by regurgitating *Past. pestis* during the act of biting and sucking blood. Epidemics in rats invariably precede human epidemics, and an extension of plague to man can be accurately foretold two or three weeks before-hand from a rising curve of infection in the rat population. Pneumonic plague, on the other hand, is intensely infectious, being directly transmitted by droplet spray infection from person to person. Doctors and nurses often acquired the disease during the Manchurian epidemic.

Pathology.—At the site of entrance, especially in resistant cases, plague bacilli may occasionally produce a primary vesicle. Generally the adjacent chain of lymph glands are acutely inflamed (primary bubo) while others are secondarily involved. Frequently bacilli enter the circulation, producing various degrees of septicæmia and in the most fulminating cases primary buboes may be absent altogether. The toxic substances elaborated by *Past. pestis* also affect the endothelial lining of the blood vessels, giving rise to congestion and hæmorrhage in the mucous and serous membranes and skin, while the cardiac muscle shows fatty degeneration and the right heart is dilated. On section the primary bubo shows intense congestion and hæmorrhage, with periglandular, gelatinous and hæmorrhagic œdema matting adjacent glands together. More distant glands, secondarily implicated, are congested and greyish-red in colour. Bacilli are numerous in the early stages and also often occur in the spleen and blood. The liver and kidneys are congested, showing cloudy swelling and fatty change, and fibrinous thrombi may be present in the Malpighian tufts. The spleen, which is two or three times its normal size, is hyperemic and often hæmorrhagic. The meninges are very congested and hæmorrhages may occur in the brain. Pneumonic plague starts as a broncho-pneumonia, but later may involve the entire lobe; pleural ecchymoses, congestion of the bronchial tree and involvement of the bronchial glands are characteristic.

Symptoms.—The incubation period varies from 2 to 12 days, generally being three to four days. In severer infections there is a marked tendency toward septicæmia and in the types of *pestis major* a sudden onset with chill or rigors, irregular high fever, nausea, vomiting, cardiac weakness and great mental prostration is characteristic. Splenomegaly and also hæmorrhagic rashes may occur, hence the ancient synonym "black death." Nine clinical types have been described.

(1) **BUBONIC.**—Prodromata include backache, pains in the limbs, and mental depression, but generally the onset is abrupt and the constitutional features severe. The blurred speech, reeling gait, and mental dullness may suggest alcoholic intoxication. Examination reveals fever, injected conjunctivæ, rapid soft pulse; the urine contains albumin, and the blood count shows a moderate leucocytosis. On the second or third day a tender primary bubo appears, the affected group of glands (femoral and inguinal = 70 per cent.; axillary = 20 per cent.; submaxillary and cervical = 10 per cent.) rapidly swelling to the size of a hen's egg or larger. Pain is severe and suppuration generally occurs during the second week. Death usually eventuates between the third and fifth day; with recovery the symptoms gradually ameliorate, but convalescence tends to be protracted. Secondary broncho-pneumonia may occur, and the sequelæ include sepsis, carbuncles, etc.

(2) **SEPTICÆMIC.**—The disease is rapidly fatal; there may be splenomegaly and slight general enlargement of lymphatic glands, but no bubo. Frontal headache, fever and vomiting are characteristic, but in the severest cases there may be only a slight rise of temperature. Cutaneous petechiæ and mælena may be noted. The diagnosis is made by a positive blood culture.

(3) **PNEUMONIC.**—Chill and a rapid rise of temperature occur at onset, followed by headache, dizziness, pains in the limbs, clouding of consciousness, pain and tightness in the chest, with cough and expectoration of a

copious, sanguineous, watery sputum teeming with plague bacilli. Dyspnoea with cyanosis, crepitations, and possibly areas of diminished resonance are found. Cardiac failure is common and death almost invariably occurs within four days.

(4) **INTESTINAL.**—A rare form, described by Wilm in the Hong-Kong epidemic of 1896, as an intestinal disorder with vomiting, incessant purging, and liquid, offensive, bile-stained stools often mixed with blood. Buboes were absent, but pathological lesions were present in the intestine.

(5) **CEREBRAL.**—In this type, which may resemble cerebral malaria, the mental hebetude characteristic of ordinary bubonic plague progresses to delirium, convulsions and coma. Definite plague meningitis has also been recorded, and may run a chronic course.

(6) **CELLULO-CUTANEOUS.**—Carbuncles appear having a necrosed and ulcerated centre, with a hard edge surrounded by a red areola, sometimes covered with minute vesicles. The condition is distinguished from coccal carbuncle by the demonstration of *Past. pestis*.

(7) **VESICULAR OR VARIOLOID.**—In this form the vesicles and pustules may be so abundant as to simulate varicella. *Past. pestis* is readily isolated from the vesicles.

(8) **ANGINAL OR TONSILLAR.**—Cervical buboes may implicate the tonsils, or violent plague tonsillitis and pharyngitis, with secondary cervical adenitis, may arise from killing vermin with the teeth—a habit of Indians in Ecuador.

(9) **ABORTIVE OR AMBULATORY (*Pestis minor*).**—Such cases are common in all epidemics: buboes develop and may suppurate or be absorbed without serious indisposition or fever, or the lymph glands may simply swell and become painful, associated with transient headache.

Complications.—Acute bubonic cases may develop plague septicæmia or pneumonia with fatal results, or after the fever has disappeared the local buboes may become indolent and take many weeks to heal. Broncho-pneumonia and septic complications such as subcutaneous abscesses, cellulitis, adenitis and parotitis sometimes ensue.

Diagnosis.—Bubonic plague early in an epidemic may need to be differentiated from climatic bubo, chancroid or syphilitic buboes, rat-bite fever, and possibly tularemia. Gland puncture reveals bipolar bacilli on culture or in smears, the crucial test being transmission of plague to the white rat by smearing infective material on its skin. In pneumonic plague herpes is absent and the sputum is sanguinolent and watery, not viscid and rusty as in pneumonia: furthermore it is teeming with plague bacilli. Septicæmic plague is diagnosable only by positive hæmo-culture.

Prognosis.—Pneumonic and pure septicæmic plague are practically always fatal. In bubonic plague the mortality rate is much higher in natives (75–80 per cent.) than in Europeans (25–30 per cent.), and axillary buboes are less favourable than inguinal ones. Positive hæmo-culture is of serious significance, and Liston showed that where the bacilli exceed 40 per l c.c. of blood, death almost invariably resulted.

Treatment.—**PROPHYLACTIC.**—This consists essentially in the destruction of rats and fleas, in preventing their coming into contact with man, and in increasing individual resistance by Haffkine's prophylactic vaccine, which gives an immunity lasting 6 to 12 months or more. The building of rat-proof houses and grain stores, rat destruction by poisoning and trapping,

fumigation of ships with sulphur dioxide and hydrocyanic gas, and evacuation of infected villages and houses during epidemics are all important measures in controlling the spread of plague.

CURATIVE.—Bed rest, liquid diet, and careful nursing are essential. Specific treatment, with large doses of antiplague serum intravenously during the first two days has been advocated (Yersin and Lustig), and more recently workers at the Haffkine Institute, Bombay, have produced a potent antiplague serum from horses which is claimed to reduce the mortality from about 62 per cent. to 25 per cent. Treatment with the sulphonamides is under trial, and favourable results have been reported with sulphathiazole and sulphadiazine. In Egypt, a combination of specific anti-serum therapy and sulphonamide medication has resulted in an appreciable reduction in the mortality rate. The buboes should be treated by hot fomentations, kaolin poultice, or belladonna and glycerin applications with incision when suppuration occurs. Morphine may be necessary for the pain. Stimulants and cardiac tonics should be used early, and intravenous injections of dextrose may be of value.

UNDULANT FEVER OR BRUCELLIASIS

Synonyms.—Malta or Mediterranean Fever; Abortus Fever; Brucellosis.

Definition.—An endemic or epidemic disease characterised clinically by prolonged fever with a tendency to long wavy relapses, splenomegaly, transient painful swellings of the joints, neuralgia and secondary anaemia. In Malta *Brucella melitensis*, conveyed in goat's milk, proved the causative organism, but indistinguishable diseases of widespread geographical distribution may be caused by the bovine and porcine strains of *Br. abortus*.

Ætiology.—Undulant fever of caprine origin is endemic in the Mediterranean basin, and has a widespread geographical distribution. The indigenous population sometimes appears to have a certain immunity to the disease as in Malta, where the Maltese, prior to the boiling of goats' milk by the garrison, were less affected than English soldiers and sailors. All ages and both sexes appear equally susceptible, and in Malta, at least, the disease proved more prevalent in the dry summer months.

Bruce, in 1886, isolated *Br. melitensis* from cases of undulant fever and experimentally reproduced the disease in monkeys. Eighteen years later it was proved that infection was conveyed in goats' milk. The organism causes a bacteraemia and may be isolated from the blood, bile, faeces, urine and milk. Primarily it is a disease of goats which, while themselves showing few symptoms, may yield a good quality milk containing large numbers of *Br. melitensis*. Other varieties include the bovine and porcine strains of *Br. abortus*, and are only distinguishable by agglutinin-absorption tests. The latter organism, which infects the chorionic cells, causes contagious abortion of swine and cattle, and produces a disease in man indistinguishable from undulant fever; it has been reported from the United States, Europe, Southern Rhodesia, South Africa, etc., is of bovine or porcine origin, and is contracted from cow's milk or contact with carcasses, infected animals or their excreta.

Pathology.—The disease is essentially a bacteraemia and organisms may be isolated from the blood, spleen and lymph glands at autopsy. The

spleen is constantly enlarged, averaging about 20 ounces in weight. Sometimes the mesenteric glands appear swollen, but there is no ulceration of Peyer's patches. The liver, kidneys and pulmonary bases show congestion, and occasionally broncho-pneumonia and glomerular nephritis are found.

Symptoms.—The incubation period is about 14 days, but may last a longer or shorter period. Monkeys develop fever five days after subcutaneous inoculation, and 15 days after ingestion of infected material. Five clinical varieties are recognised: (1) Ambulatory; (2) Undulant; (3) Intermittent; (4) Continuous; and (5) Malignant.

(1) **AMBULATORY OR MILD.**—In some cases the symptoms are so slight that infected persons go on with their work as usual; in others there are slight fever and minor symptoms which disappear rapidly, serum tests alone indicating infection. Out of 525 dock hands examined by Shaw in Malta, 79 gave positive agglutinin reactions, whilst 9 out of 22 of those specially tested showed the organism either in the blood or urine or both. Such cases constitute human carriers.

(2) **UNDULANT OR ORDINARY.**—The onset is generally insidious like typhoid, and the symptoms often resemble those seen in other fevers, but the temperature chart is characteristic. Bouts of fever lasting two or three weeks alternate with periods of remission, so producing the typical undulant fever chart. Illness in the ordinary case lasts three to four months, the extremes being three weeks to two years. The fever is often associated with profuse sweating, lassitude, secondary anaemia, debility and transient painful swelling of the joints resembling rheumatic fever, but not responding to salicylates. Enlargement and tenderness of the spleen and liver also occur, and neuralgic pains, especially involving the intercostal and sciatic nerve, are common. The tongue has a central white fur, and anorexia, flatulence, abdominal discomfort and constipation are often troublesome features. The leucocyte count is generally normal, but there is a relative lymphocytosis; the urine may contain albumin. After running a more or less chronic course, the remissions become more prolonged, the febrile exacerbations less high, and recovery gradually ensues. No patient should be regarded as convalescent, however, until the temperature and pulse have been normal for at least a fortnight and all other symptoms have disappeared. Neuritis, debility and anaemia may persist for a considerable period.

(3) **INTERMITTENT TYPE.**—There is a swinging temperature resembling benign tertian malaria, a normal morning temperature being succeeded by a sudden afternoon rise to 105° F. or higher, accompanied by chilliness and a definite rigor; by evening the temperature falls again with drenching sweats. The condition is differentiated from malaria by the absence of parasites.

(4) **CONTINUOUS TYPE.**—Here there is continuous fever for a period of from one to three months.

(5) **MALIGNANT TYPE.**—The patient is attacked suddenly with high fever, severe generalised pains, diarrhoea and vomiting. Broncho-pneumonia, cardiac weakness and a typhoidal state frequently develop, while hyperpyrexia may precede death.

Complications.—These include bronchitis, broncho-pneumonia, neuritis, parotitis, orchitis in the male and mastitis in the female. Purpura and

suppurative osteitis have also been described. Menorrhagia, abortion or premature labour may also result.

Diagnosis.—The differential diagnosis includes the enteric fevers, acute rheumatism, malaria, kala-azar, tuberculosis, subacute bacterial endocarditis, thoracic lymphadenoma associated with the Pel-Ebstein syndrome, amœbic abscess of the liver and occult pyogenic infections. Macroscopic agglutination reactions are of great diagnostic value after the first fortnight of fever, the serum being tested in an ascending series of dilutions (1/25–1/1000) against dead *Brucella* emulsions. Absorption of agglutinin may be necessary to distinguish infections with *Br. melitensis* and *Br. abortus* respectively. Blood culture in liver infusion broth is often positive for *Br. melitensis*, and the period of examination should extend over a fortnight before reporting the result as negative. *Br. abortus* must be grown in an atmosphere of 10 per cent. carbon dioxide or, better still, 1 c.c. of suspected blood is inoculated into the peritoneal cavity of a guinea-pig, culture from the peritoneal cavity being generally positive in about a week and from the spleen at a later date. Burnet's intradermal test is frequently positive; it is characterised by the development of localised redness and œdema some six hours after inoculation, the reaction lasting one to two days.

Prognosis.—Mortality rates of from 2 to 9 per cent. have been recorded. Death generally results in malignant cases during the first three weeks of fever. At any time, however, fatal recrudescence may occur, a typhoidal state, broncho-pneumonia, cardiac failure and hyperpyrexia being grave signs. Chronic cases may present great debility, emaciation, anæmia and neuritis.

Treatment.—**PROPHYLACTIC.**—Laboratory workers should be very careful in handling *Brucella* cultures for, as in tularæmia, infection is easily acquired. Adequate boiling of goats' milk renders it safe, but its prohibition in endemic centres and the destruction of infected animals are more effective. Cream and cheese may also convey infection. In the case of *B. abortus* the disease may arise from cows' milk or the carcasses or excreta of bovines and porcines.

CURATIVE.—Careful nursing and a nourishing dietary which should include milk puddings, eggs, fish, fruit juice, yeast and other vitamin-containing foods, are desirable. Cool sponging is indicated whenever the temperature exceeds 103° F. Specific therapy is still under trial. Anti-undulant fever serum has been favourably reported on, as has also immune-transfusion in the form of a direct transfusion of 500 c.c. of compatible blood from a recovered case. Autogenous vaccines and "brucellin" are of doubtful value. A course of sulphonamide terminates the fever in some cases, but recurrences are not infrequent. Cures are recorded following T.A.B. vaccine intravenously, commencing with 50 millions and working up to 250 millions, injections being given every fourth day. Various symptoms and complications, such as sleeplessness, headache, arthritis and orchitis, should be treated as they arise.

BARTONELLOSIS

Two clinical forms of Bartonellosis are now recognised, namely, (1) Oroya fever, in which there is a generalised infection with *Bartonella bacilliformis*; and (2) Verruga peruviana, in which there are local lesions in the skin.

OROYA FEVER

Synonyms.—La Maladie de Carrion; Carrion's Disease; Generalised Bartonellosis.

Definition.—An acute infectious disease caused by *Bartonella bacilliformis*, characterised by irregular remittent fever, headache, tenderness over the bones and a severe anæmia of megalocytic type; fatalities are frequent.

Ætiology.—Oroya fever is limited to valleys on the western slopes of the Peruvian Andes between 1800 and 9000 feet. Both sexes are susceptible and children may be attacked. Carrion (1885) inoculated himself from a verruga nodule and died of Oroya fever a month later. Barton (1909) found rod-like organisms in the red cells in this disease; they were also numerous in the endothelial cells of the lymphatic glands. Noguchi (1926) cultured the organism and subsequently experimentally infected monkeys, the susceptible animals developing a condition like Oroya fever, the most resistant ones, lesions of verruga peruviana only. The disease is most prevalent from January to April, when insect life is most plentiful. Transmission is probably by sand-flies of the species *Phlebotomus noguchi* and *P. verrucarum*.

Pathology.—The skin is yellow, the lymphatic glands, liver and spleen are enlarged, and the long bones filled with red marrow. The heart shows fatty degeneration, the liver zonal necrosis, while endothelial cell hyperplasia is common. Petechial hæmorrhages occur in the skin and serous sacs.

Symptoms.—The incubation period is about three weeks, the onset being fairly rapid with malaise and headache. Irregular remittent fever somewhat similar to paratyphoid, pains in the joints and tenderness over the long bones are characteristic, while the spleen and lymph glands may be enlarged. Grave anæmia of hæmolytic megalocytic type rapidly develops, in the severe cases the red cells falling as low as 1,000,000 per c.mm. The colour index often exceeds 1.0, and polychromatophilia, poikilocytosis, normoblasts, erythroblasts and even megaloblasts are evident in blood smears. The indirect van den Bergh reaction shows hyperbilirubinæmia. Unlike pernicious anæmia it presents a marked leucocytosis with a shift to the left, myelocytes and meta-myelocytes being present, lymphoblasts, Turck cells and the Reider type of lymphocyte are also common (Monj1 and Weiss). Œdema of the legs, cardiac murmurs and retinal hæmorrhages may occur, while hæmorrhagic manifestations of the skin and gums, and coma with subnormal temperature are met with in severe cases. The acute stage of the illness lasts some two weeks, and may either terminate fatally or pass on into the eruptive stage with chilblain-like nodules, i.e. verruga peruviana.

Diagnosis.—The rod-shaped bacilli are only demonstrable in the blood smears in severe infections, and Noguchi preferred culturing *Bartonella bacilliformis* for this reason. The limited geographical distribution and the rapid onset of a febrile megalocytic anæmia are important features in diagnosis, but malaria, paratyphoid, rheumatic fever and tuberculosis may need to be differentiated.

Prognosis.—A great variation in the intensity of the infection in different patients is noted. Mild cases recover, but in well-established cases of Oroya fever the mortality rate is from 30 to 40 per cent.

Treatment.—Sand-fly bites should be avoided by sleeping under netting having a 22-to-the-inch mesh.

Specific treatment with an arseno-antimony compound, Sdt. 386B, is now available. This drug, introduced by Kikuth, is given intravenously in a dosage of 0.1–0.3 g. on three or more occasions. *Bartonella* rapidly disappears from the blood, and the anæmia improves. In some cases a total of 5.7 g. was tolerated without untoward effect.

VERRUGA PERUVIANA

Synonym.—Localised Bartonellosis.

Definition.—This is the eruptive stage of Oroya fever in which host resistance is high; miliary and nodular lesions may result which show a marked tendency to ulceration and hæmorrhage.

Ætiology.—The disease may be transmitted by local inoculation from monkey to monkey, and Noguchi has successfully cultured *Bartonella bacilliformis* from the local lesions. Only specially susceptible animals show the systemic manifestations associated with Oroya fever.

Pathology.—The pathological lesion is a very vascular, infective granuloma showing a marked tendency to ulceration and hæmorrhage. The endothelial lining of both lymphatics and capillaries proliferates. Plasma cells and fibroblasts appear in an œdematous, delicate reticulum containing numerous blood vessels around which angioblasts undergoing mitosis may accumulate; the late appearances may simulate fibrosarcoma.

Symptoms.—The incubation period varies from two to five weeks, when rheumatic-like pains develop in the limbs and joints associated with moderate fever which generally subsides within a few days. Subsequently an eruption of tubercles and nodules occurs. The *miliary type* of lesion commences as a red macule which gradually develops into a flat or pedunculated wart-like structure about the size of a small pea; the lesions occur most frequently on the face and extensor surfaces of the arms and legs, but similar ones may involve the mucous membranes of the eyes, nose, pharynx and larynx, giving rise to cough, hoarseness, epistaxis and even sudden death. The *nodular type* of lesion may attain the size of a chestnut; these tumours often ulcerate, forming large, bleeding, fungating masses situated in the flexures of the joints and appearing in successive crops. Little difficulty is experienced in diagnosis and fatal results are rare, though the disease may last two to three months.

Treatment.—When the nodules ulcerate they should be dressed with antiseptics, and if they undergo necrosis or hæmorrhage severely they may be excised. Intravenous injections of Sdt. 386B, should be administered.

LOBAR PNEUMONIA (see p. 1245).

BRONCHO-PNEUMONIA (see p. 1256).

BOTULISM (see p. 429).

B. DISEASES CERTAINLY, OR ALMOST CERTAINLY, OR POSSIBLY DUE TO FILTRABLE VIRUSES

INTRODUCTION (see pp. 8-9)

THE COMMON COLD

Synonyms.—Acute Coryza ; Cold in the Head.

Definition.—An inflammatory process affecting the upper respiratory tract in which the air sinuses and tubes in connection therewith may also be involved.

Ætiology.—Colds are very common in the damp variable weather of the autumn, winter and spring in temperate climates. Susceptibility to infection tends to diminish with age, yet shows great variation amongst different individuals and even in the same individual under different conditions. Both sporadic and epidemic forms are met with, and infection may spread through a community with great rapidity. Amongst important predisposing causes are frequent changes of atmosphere, as by entering and leaving hot, stuffy, ill-ventilated, crowded rooms; the presence of a focus of chronic infection in the upper respiratory tract, e.g. adenoids, infected tonsils and chronic cranial sinusitis; structural anomalies which interfere with free ventilation of the nose, e.g. deflected septum, and polypi; and chronic irritation of the mucosa by smoke, dust or chemicals in sprays, etc. Very little is known of the exact pathogenesis, but there would appear to be at least two factors. A filtrable virus seems to be primarily responsible, aided by other organisms which set up a secondary infection, either severally or together. The virus is air borne, and spread is by droplets expelled from the nose and naso-pharynx by sneezing, speaking, coughing, etc. The portal of entry is the nasal or pharyngeal mucosa and, possibly, the conjunctival sac; infection develops locally via the submucous lymphatics to neighbouring areas, all or one of which may bear the brunt of the inflammation, the resulting clinical picture being an acute rhinitis, sinusitis, pharyngitis, laryngitis or tracheitis. The secondary infection may be by organisms already present as normal inhabitants on the inflamed mucosa, e.g. pneumococcus, streptococcus viridans or micrococcus catarrhalis; or pathogenic bacteria generally conveyed by droplet, e.g. hæmophilus influenzae, streptococcus hæmolyticus, staphylococcus pyogenes. It is impossible to be dogmatic as to which signs and symptoms are consequent on the primary or the secondary infection respectively; it may be that variations in symptoms and the degree of the accompanying toxæmia in different individuals in the same epidemic are due to variations in the secondary infection. Local infection induces vasodilatation and œdema in the spongy submucous tissues and engorgement of the mucosa, with outpouring of mucoid secretion, which soon becomes muco-purulent in character. The swelling may cause obstruction to the outlet of an air cell, particularly in the ethmoid or sphenoid, or to the duct of the frontal sinus; absorption of air behind such an obstruction may be responsible for a "vacuum headache," or if the Eustachian tube is involved to deafness and vertigo; when an air sinus

is implicated in the inflammatory process and its opening is obstructed, local pain and "distension headache" are prone to follow.

Clinical Features.—The incubation period varies considerably but is usually between 12 and 48 hours; it would appear to be shortened by chilling of the body or exposure to wet. The first symptom is often a stuffiness in the nose, which is soon accompanied by a pricking sensation and sneezing; a profuse discharge, at first mucoid but which within 12 hours becomes mucopurulent, may lead to excoriation of the anterior nares. Taste and smell are impaired. Pharyngitis and tonsillitis are common, and there may be some follicular exudate on the tonsils. If the inflammation spreads to the larynx, the voice becomes hoarse, and a tracheitis will induce a painful irritating cough which may be paroxysmal, especially at night, and retro-sternal soreness. Symptoms are confined in the main to the respiratory tract. Constitutional disturbance is usually slight, though in some epidemics the temperature may reach 102° F. for 48 hours. In such cases pain in the back and limbs, and a sense of exhaustion may be experienced. The catarrh slowly subsides, and the patient is usually free from symptoms in from 4 to 7 days. Immunity is shortlived.

Complications and Sequelæ.—When these arise, they are consequent on the secondary infection. Some suffusion of the conjunctivæ is common. Herpes around the nostrils and on the lips may be extensive during the acute stage. Suppuration in the accessory sinuses or an acute otitis media may occur. Bronchitis, especially in those patients liable to that disease, may flare up and persist for a long time. Broncho-pneumonia is the most serious complication, and not a few cases of pulmonary tuberculosis follow a "neglected cold."

Treatment.—**PROPHYLACTIC.**—The avoidance of infection in the community is well-nigh impossible, but much may be done by efficient ventilation and fresh air. When knowingly exposed to infection, it is a good rule to keep the mouth shut as far as possible, and on leaving some individuals have faith in taking a pinch of snuff into each nostril. A full dose of quinine is certainly sometimes of value when symptoms threaten: *e.g.* liq. quiniæ ammon., min. 120, tinct. opii camph., min. 60, spir. ammon. aromat., min. 60, in half a tumbler of water; which may be repeated in 4 hours if necessary. Stock anti-catarrh vaccine undoubtedly has a prophylactic value in some seasons; though the results of inoculation may appear encouraging through one winter, they may be disappointing the next, or *vice versa*. If inoculation is to be employed in this country it is recommended that four doses ($\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$ and 1 c.c.) of the St. Mary's Hospital vaccine should be given subcutaneously at weekly intervals during September, followed by 0.5 c.c. once a month throughout the winter. In those patients in whom recrudescence, relapse or repeated re-infection appear to be associated with a chronic inflammatory focus in the upper respiratory tract, that focus should be eliminated by surgical means; in these conditions vaccine therapy is not included in the first line of attack.

Discharge from the nose and throat during the first 48 hours is highly infective; handkerchiefs, pillow-cases and other materials likely to be soiled should be soaked in disinfectant.

GENERAL.—Though isolation is, in theory, admirable both for the protection of the patient and for limiting the spread of the disease, in practice

it can be enforced but seldom. If there is much constitutional disturbance, if the patient suffers from the frailty of old age, or active pulmonary disease, or diabetes mellitus, or subacute nephritis, or heart failure, the common cold must be taken seriously and the patient confined to bed until free from symptoms for 48 hours.

Treatment is entirely symptomatic. In the early stage stuffiness of the nose and throat may be relieved by inhalation for 10 minutes from a jug containing boiling water $\frac{3}{4}$ pint and cold water $\frac{1}{4}$ pint (or a pint of boiling water allowed to stand for 7 minutes), tr. benzoini co., min. 60, and menthol grs. 2. This should not be done just before the patient goes out of doors. A solution of 2 per cent. silver nitrate or colloidal silver may be used as a spray. Amphetamine (benzedrine) and ephedrine may give temporary relief to symptoms by shrinking the congested nasal mucosa; they should not be used to excess. Hoarseness of voice and the retrosternal soreness of tracheitis may be helped by local counter-irritation; a piece of active mustard plaster the size of half a crown applied to either side over the thyroid cartilage for 20 minutes, or heat in some form, may serve to restore a lost voice. Diaphoresis is encouraged by aspirin, Dover's powder and a hot drink at bedtime. Drugs of the sulphonamide group should not be administered as a routine; only when a pyogenic complication develops should the appropriate drug be given, and in full dose.

HORDER.
A. E. GOW.

MEASLES

Synonym.—Morbilli.

Definition.—A specific highly infectious fever, characterised by catarrh of the respiratory passages, the presence of Koplik's spots on the buccal and other mucous membranes, a distinctive widespread papular eruption on the skin and a special liability to pulmonary complications.

Ætiology.—Measles is of world-wide distribution. Both sexes are equally liable. It is extremely infectious, and there is little evidence that natural immunity ever occurs, but a temporary active immunity may be acquired during epidemics without an overt attack. When introduced among unprotected communities it spreads with appalling rapidity to persons of all ages, and causes many deaths. More than half the attacks of measles occur in the first 5 years of life, and seven-eighths of all cases occur in children under ten. There is a temporary passive immunity of the newborn child, possibly due to transmitted maternal immunity, which gradually wanes after the first 3 months, and infants under 6 months rarely take the disease. Early incidence is most pronounced in poor and crowded communities; among the middle classes it is delayed to school age or later. When measles occurs in a pregnant woman abortion or premature delivery often results, and the infant may also exhibit the rash, usually in the same stage as the mother (*Congenital Measles*). The disease is endemic in large cities, and cases are numerous from December to March, again increasing in May and June. Epidemics recur every two or three years, and every tenth year an especial incidence is said to be noticeable.

The virus resides in the secretions of the respiratory tract and direct

infection is the rule, very intimate contact is not essential. Infectivity may be present 5 days before the appearance of the rash, possibly longer, and then rapidly declines. Only on rare occasions do intermediaries convey the infection, and rooms and fomites do not retain it for more than a short period. There is no evidence incriminating water, milk or other articles of food.

Pathology.—The causal agent is a filter-passer, and evidence accumulates that it is a virus. A small diplococcus, isolated by Ruth Tunnicliff, which forms green colonies on blood-agar, was at one time suspect. The disease has been reproduced in man and monkeys by inoculation with blood, bronchial secretions or tears. The infective agent can be cultivated in chick embryos. The most striking visceral change is broncho-pneumonia. Secondary infections chiefly with hæmolytic streptococci are common. Catarrhal or ulcerative laryngitis may be found. The bronchial glands are inflamed and the lymphoid aggregations of the small intestine may be very conspicuous. Active tuberculous lesions are not uncommon.

Symptoms.—*Incubation.*—The rash appears on the fourteenth day of infection, sometimes a day earlier or a day later, but it may be delayed in patients who have been injected with the serum of convalescents. This interval is more constant than that which elapses between infection and the first catarrhal symptoms. Reckoning to the onset of fever and catarrh 9 or 10 days usually pass. In some cases the incubation period is slightly febrile and a transitory feverish catarrh with fleeting rash has occurred even a few hours after exposure to infection (Goodall's *illness of infection*). A polynuclear leucocytosis is characteristic of the incubation stage. Slight enlargement of the cervical, inguinal, axillary and other glands may precede the eruption. Koplik's spots on the buccal mucosa may precede the rash by 2 or 3, sometimes by 5, days. Prodromal rashes are not uncommon; a precocious macular eruption is the commonest, but a punctate scarlatiniform erythema is the most important, since it simulates scarlet fever. It is apt to appear on the second day of invasion. An urticarial rash may also occur.

Invasion.—This is characterised by catarrh of the respiratory tract, fever and the outbreak in the mouth of Koplik's spots. It culminates in the appearance of the skin eruption. Sneezing, irritating cough, watery eyes and conjunctival injection are the early signs. There is chilliness, and the temperature may reach 103° F. by the end of the first day. Photophobia and sharp diarrhoea may occur. In the early stage of invasion slight blotchiness of the skin about the mouth and nose may be evident. The cutaneous rash usually appears on the fourth day, and a deceptive remission of symptoms and fall of temperature sometimes occur just before its outbreak. In some instances laryngeal symptoms are marked during the invasive stage, and give rise to suspicion of diphtheria; exceptionally, catarrh is insignificant, and an attack of severe simple tonsillitis is simulated.

Koplik's spots are of great importance in the early diagnosis, since they are recognisable some 72 hours before the rash, with the appearance of which they rapidly disappear. They are minute superficial specks of a bluish-white tinge, and show a tendency to aggregate into small clusters or granular patches. Their common site is on the inner aspects of the cheeks, opposite the line of apposition of the molar teeth; but they may be more widely scattered over the buccal mucous membrane, on the inner surfaces of the

lips, and on the conjunctivæ. There is evidenceth at they also occur on the mucosa of the colon. Sometimes they are surrounded by bright red areolæ. In addition, the mucous membrane of the mouth becomes congested and dusky, and a decided blotchy enanthema may here precede the cutaneous eruption.

Period of eruption.—With the approach of the rash the symptoms become aggravated. The temperature (Fig. 4) rises sharply, it may be to 104° or 105° F. The hurried respiration and slight cyanosis may suggest bronchopneumonia. Diarrhœa may persist, and sometimes urinary irritation is noticeable. The nasal and conjunctival discharges become more purulent. The eruption makes its first appearance about the brow, behind and below the ears, and in the circumoral region. Rarely, it appears first on other parts, such as the buttocks, thighs or wrists. It spreads rapidly, sometimes after a short hesitation, over the face, neck, trunk and extremities, and is usually fully out on the fifth or sixth day of the attack. Small brownish macules are the first elements, but they soon become papular, and show a tendency to fuse into groups with irregular sinuous outlines. Profuse eruptions may become confluent on the face, neck, back and extensor aspects of the limbs. Petechial hæmorrhages in the rash are not uncommon. The skin is usually moist and exhales a peculiar musty smell. Rarely, it is hot and dry. Itching or burning sensations may accompany the rash. The eruption fades in the order of its appearance, and usually disappears in the course of two or three days; but brownish staining may persist for some time, particularly on the back. A fine branny desquamation speedily follows. At its first appearance, the rash may fail for a time to spread; retrocession is also sometimes observed. A badly developed and retarded rash is characteristic of some severe attacks, and in asphyxial states the rash may be quite cyanotic. As the rash develops, the temperature continues to rise, reaching its maximum with the climax of the eruption in from 24 to 48 hours. When the rash begins to fade, the temperature falls more or less abruptly by a crisis which is rather prolonged. The pulse-rate is increased in proportion to the fever, but the respiration is disproportionately rapid. The catarrhal symptoms also reach their greatest

FIG. 4.—Measles. Showing the remission in invasion stage and the abrupt termination.

intensity at the height of the eruption. Headache, slight delirium, insomnia and a feeling of intense wretchedness are characteristic of this period. The throat may be sore, the buccal mucous membrane show an intense catarrh, and the glands at the angle of the jaw become tender. The tongue at first is heavily coated, but before long red papillæ are evident, and when peeling is complete a clean, red papillated tongue, very like that of scarlet fever, may often be seen. With the crisis rapid amelioration of all symptoms should occur.

The blood now shows a leucopenia with a high percentage of large lymphocytes. All complications induce a polynuclear leucocytosis.

The urine presents the ordinary febrile characters. Transitory albuminuria may occur. Ehrlich's diazo-reaction is nearly always present, and is most marked when the temperature begins to fall. An acetone reaction is obtained in most cases.

VARIETIES.—Attacks may be mild or severe. Some of the mildest attacks are abortive, the rash failing to appear, and only Koplik's spots giving a clue to the disease. Severe attacks are classified as toxic, pulmonary and hæmorrhagic. The *toxic type* includes those cases in which the patient may succumb during the eruptive period without evident complication. Ill-defined rashes, high fever, muscular tremor, delirium, dyspnoea and circulatory failure are characteristic features. In the *pulmonary type* the infection falls with especial stress upon the lungs. The temperature is high, the respirations rapid and hissing, and the condition suggestive of slow asphyxia. Consolidation of the lungs cannot be detected, but rhonchi are present everywhere, accompanied by fine crepitations. A stuporose condition may precede death or terminal convulsions may occur. The true *hæmorrhagic type* of measles is rare. The patient may bleed from the mucous membranes with hæmorrhages into the skin and subcutaneous tissues. Recovery takes place in some instances. Hæmorrhage into the rash has not the same grave significance.

Complications.—These are numerous, but those involving the respiratory tract, the middle ear and the bowel are the most important.

Laryngitis may accompany the onset, develop during the eruption, or appear early in convalescence. Arising in the invasive stage it may simulate laryngeal diphtheria. Laryngitis is more common during the eruptive period, and may persist for some days—it may be complicated by laryngeal ulceration, sometimes by œdema of the glottis; but necrosis of the laryngeal cartilages and abscess formation are rare. Severe laryngitis developing during convalescence should always arouse suspicion of diphtheria.

Bronchitis is often present during the eruptive stage, but broncho-pneumonia is a much more serious complication, and is a common cause of death. Its incidence is favoured by climatic conditions, overcrowding and contact with similar cases. It is generally attributed to secondary pneumococcal or streptococcal infection; but, especially when occurring early in the infection, it is rightly regarded as due to measles itself. This early broncho-pneumonia is associated with a high temperature (Fig. 5) and considerable toxæmia. It is suffocative in type, and the lung signs are rather those of capillary bronchitis than of consolidation. During the eruptive stage, broncho-pneumonia should be suspected if the temperature fails to fall with subsidence of the rash, and the pulse remains quick and respiration rapid. It may clear up in a week or ten days, but often persists for weeks, or relapses. The

temperature chart often shows remarkable daily remissions and exacerbations which may lead to suspicions of tuberculosis. The mortality is serious, since one-third or one-half of the children attacked are said to die. Feeble infants succumb rapidly, and in those who recover convalescence is protracted. True lobar pneumonia is uncommon. Massive collapse of the lower lobe of a lung has been described; its onset is sudden with intense dyspnoea, cyanosis and cardiac failure. It is distinguished from pneumonia by the feebleness of the breath sounds, upward displacement of the diaphragm and dislocation of the heart towards the affected side. Rarely mediastinal and subcutaneous emphysema have occurred. Effusions into the pleura have been noticed in some epidemics, and empyema may follow. Fibrosis of the lung and bronchiectasis often originate in the broncho-pneumonia of measles.

FIG. 5.—Temperature chart in a case of measles with protracted broncho-pneumonia ending in complete recovery.

Rheumatic arthritis with pericarditis, endocarditis and sometimes chorea have been observed.

Blepharitis and phlyctenular ulcers are common sequels. In cachectic children intense conjunctivitis may lead to ulceration and even perforation of the cornea.

The stomatitis of measles occasionally becomes ulcerative. A gangrenous inflammation (*noma*) may attack the lips, cheeks, vulva or other parts. A discoloured patch appears on the mucous membrane and quickly ulcerates, extending both in depth and breadth. A zone of inflammatory induration surrounds the lesion, and a fetid odour is given off. *Noma* is terribly destructive both to soft parts and bone, and is very fatal. It occurs in debilitated children, and is attributed to secondary infection. Vincent's spirilla and fusiform bacilli are often present. It is said to be sometimes due to the Klebs-Loeffler bacillus. Pronounced leucopenia may accompany it.

Otitis media is frequent. It may be catarrhal or suppurative; the suppurative form is more common in children, and is responsible for much chronic ear disease. Mastoid inflammation may occur, and deafness may result.

Cutaneous eruptions of eczematous, impetiginous or pustular type are common. Sometimes they are widespread, and very resistant to treatment.

Enlargement and suppuration of the cervical glands, enterocolitis and ascites are rarer complications.

Encephalo-myelitis of a demyelinating or of an acute hæmorrhagic type (see p. 1605) may occur towards the end of the first week, with a course which is either rapidly fatal or tends to spontaneous recovery. Meningeal symptoms or convulsions may signalise its onset. Hemiplegia, aphasia, coma or mental defect are rare. Myelitis, sometimes of the ascending form, has been known to occur; also symptoms suggestive of disseminate sclerosis. Sometimes the cranial nerves are attacked. Paralysis of extra-ocular muscles, papilloedema and optic atrophy have all been encountered. The peroneal type of muscular atrophy may follow measles.

Measles especially favours the activation of tuberculous foci hitherto latent in the bronchial glands or elsewhere. Caseous broncho-pneumonia, miliary tuberculosis of the lungs, or general tuberculosis with meningitis may follow immediately or occur after a quiescent period. Measles often occurs in close association with whooping-cough, diphtheria and scarlet fever.

Relapse in measles is rare. Second attacks, although uncommon, undoubtedly occur, and some unfortunate individuals appear never to acquire any lasting immunity. Fourth, and even seventh, attacks are known.

Diagnosis.—In the prodromal stage, measles may be mistaken for ordinary naso-pharyngeal catarrh or even tonsillitis. If laryngitis is pronounced, and the child croupy, diphtheria may be simulated. Mastoid operations, excision of the tonsils and of the appendix sometimes are performed precipitately before the true nature of the infection is recognised. Febrile symptoms and loss of weight during the incubation stage may be erroneously attributed to tuberculous infection. The prodromal scarlatiniform rash may lead to confusion with scarlet fever. These errors may be avoided by bearing in mind the possibility of measles, inquiring for possible exposure to infection, and particularly by a careful search for Koplik's spots, and shottiness of the posterior cervical glands. The pre-eruptive fall of temperature and recession of the catarrhal symptoms before the appearance of the rash should be borne in mind, and not lead to premature relaxation of precautionary isolation.

In the eruptive stage, the fevers with which measles may be confused are rubella, small-pox, and perhaps typhus.

Rubella is distinguished by the trivial nature and brevity of its prodromal symptoms; the slightness or absence of catarrh and cough; the insignificant fever; the absence of Koplik's spots and of stomatitis; and the presence of tender enlargement of the posterior cervical, mastoid and occipital glands. The rash of rubella is smaller, pinker and more discrete; but a scarlatiniform stage may supervene. The patient never feels or appears so ill as in ordinary measles. A previous attack of ordinary measles generally excludes that disease.

Small-pox may be heralded by a prodromal rash of morbilliform character, which may have a similar distribution to that of measles, save perhaps on the face. Catarrh, stomatitis and Koplik's spots, however, are absent, and

the onset is more abrupt, and more likely to be signalled by such symptoms as backache, acute shivering, vomiting and prostration.

Measles may, on the other hand, be mistaken for the early eruptive stage of small-pox, for in both an illness for a few days may precede the appearance of a papular rash on the face and upper parts of the body. Catarrh, Koplik's spots and distribution of the rash about the ears, circumoral region, and margins of the hairy scalp are in favour of measles. The temperature, too, continues to rise until the maximum efflorescence, whilst that of small-pox falls with the appearance of the rash. As the rash develops, the shottiness of the small-pox papules and the peculiarities of their distribution and evolution become apparent.

Typhus fever may be simulated by measles when the rash of the latter is receding and dusky, and lung complications are present; but the rash of typhus rarely invades the face, which is always affected in measles. The Weil-Felix reaction also is valuable.

Septic rashes in scarlet fever are often morbilliform; but their distribution does not conform to that of the measles rash. *Serum rashes*, *food rashes* and *drug eruptions* may assume a measly character; but these rashes often prove to be polymorphic when the whole body is examined, as it should be, and, besides, other signs of measles are wanting.

The *macular syphilide* is distinguished by the absence of respiratory catarrh and of Koplik's spots. History of exposure to venereal infection, a chancre and the accompanying throat symptoms afford a clue. The Wassermann test should be employed.

Prognosis.—In different epidemics the death-rate may vary from 1 or 2 to over 50 per cent. Measles is most fatal to infants and young children, 70 per cent. of the mortality occurring in children under 3 years of age. After the fourth year the death-rate is low. Rickets, tuberculosis, congenital syphilis, malnutrition and chronic bowel complaints are unfavourable factors, and the disease is more fatal among the poor. In the cold season of the year the tendency to respiratory complications is more marked. When the infection occurs in conjunction with whooping-cough or chronic lung disease the mortality is high. Diphtheria is apt to assume the laryngeal form, and is an especially fatal complication. Considerable toxæmia with high fever, cyanosis, muscular tremor and diarrhoea point to a severe attack. Laryngitis, capillary bronchitis and broncho-pneumonia are serious. Cerebral symptoms, such as prolonged stupor or convulsions, are of bad augury. Remarkable recovery has been noticed in some cases of ascending myelitis.

Treatment.—**PROPHYLACTIC.**—Measles is chiefly disseminated by schools. The difficulty in controlling outbreaks of measles arises from the fact that it is extremely infectious, and the infectivity is present in virulent form for 4 or 5 days before the rash appears. Notification and school closure have been tried with poor results. The best method is to make provision for the early recognition of suspicious symptoms in contacts or to exclude those who have not had measles previously, for a period covering the ninth to the sixteenth day after the occurrence of the first case.

In the home, when measles occurs those who have had the disease need not be excluded from school—save from infant classes, but those presumably susceptible should either be excluded for over 16 days from exposure to infection, or, if allowed to attend, be subjected to daily examination.

In ward outbreaks children who have not had measles should be passively immunised and if possible isolated, or, at all events, segregated in small groups.

Serum prophylaxis.—Intramuscular injection of the blood serum of healthy convalescents from measles into susceptible contacts produces a passive immunity, which lasts about a month. Injection during the first 5 or 6 days of the incubation period prevents measles if the dose is adequate. Injection after the sixth and before the ninth day will modify the severity of attack, and allow the development of an *active* immunity which is lasting.

The dose is 2 c.c. for each year of a child's age up to a maximum of 10 c.c. ; more is needed for adults or if the serum is injected late. In children under 3 years of age it is better to prevent the attack altogether. The most potent serum is obtained from the sixth to the ninth day after defervescence. The donor must be free from syphilis, malaria and tuberculosis, and must not be incubating any other infectious disease. The serum of adults, presumed to have had measles, but not recently, is of some value, but the dose should be doubled. A placental globulin extract has been prepared for use in the same way.

If measles follows the subcutaneous injection of immune serum the rash fails to erupt at the site of injection ; this is the *Debré phenomenon*. Immune serum does not blanch the developed rash. A disquieting feature is the occasional occurrence of infective hepatitis after the administration of convalescent measles serum, sometimes after so long a interval as 3 months.

Systematic taking of temperatures and examination for Koplik's spots and catarrh facilitate early detection of the disease, when patients are under close observation. The wilful exposure of children to the contagion of measles is unjustifiable, as the nature of the resulting attack can never be predicted.

Sixteen days' quarantine from the date of last exposure to infection is usually deemed sufficient, but, owing to the trivial nature of the prodromal symptoms it is better, in the case of schools, if quarantine is imposed at all, to allow a period of 3 weeks to elapse, especially if serum prophylaxis has been attempted. Convalescent patients in the absence of complications are quite free from infectivity at the end of a fortnight from the appearance of the rash.

CURATIVE.—The patient must be confined to bed during the febrile, and also during the prodromal stage, if this is recognised in time. The sick-room should be kept at a temperature of 60° to 65° F., and ventilation effected by means of open windows ; an open fire is also an advantage. The photophobia calls for the avoidance of direct light. Clothing should be light and consist of a flannel or woollen nightdress ; this is sufficient to prevent chill, allows the respiratory muscles full play, and encourages the evaporation of perspiration. Strict attention should be paid to cleansing the mouth and teeth, and the regulation of the bowels. During the febrile stage the diet should be restricted to milk, diluted if necessary with barley water. Tea may be allowed, and fruit juices or barley water given to assuage the thirst.

Twice a day during the febrile period the patient should be washed with tepid water ; but should the attack assume a toxæmic form, accompanied by high fever and delirium, cold sponging or the use of the cold pack is advisable.

Amidopyrin, given early, is said to abort the disease but may induce agranulocytosis. The hot mustard bath is useful for children when pyrexia is accompanied by indications of circulatory failure.

Laryngitis in the early stage is relieved by steam and the use of a simple expectorant mixture, to which a sedative may be added. The croupy symptoms usually subside without necessitating tracheotomy or intubation. The possibility of the presence of diphtheria renders a bacteriological examination essential.

Laryngitis which persists after the eruption may be alleviated by the inhalation of compound tincture of benzoin or lysol in the strength of 60 minims to the pint of boiling water. The cough is relieved by a simple linctus, or one containing codeine or other sedative. Late laryngitis if diphtheritic needs antitoxin. Bronchitis and broncho-pneumonia call for prompt treatment. A jacket of Gamgee tissue should be applied. If the cough is dry and irritating, steam often relieves. An expectorant mixture containing ipecacuanha and a small quantity of potassium iodide is useful. Sometimes a single mustard and linseed poultice gives great relief. As the cough becomes looser, steam should be discarded and free ventilation arranged. It is well to separate cases with broncho-pneumonia from others, as the condition is believed to be infectious. Treatment of the broncho-pneumonia of measles in the open air, where circumstances and weather permit, gives excellent results. Oxygen is valuable where there is much respiratory distress and cyanosis. Cardiac dilatation is an indication for the application of leeches. Frequent small meals are preferable to overloading the stomach.

Conjunctivitis should be met by bathing the eyes with boric lotion and the application of boric ointment to the lids. In severe cases, drops of silver nitrate solution, 2 grains to the ounce, should be instilled night and morning, or 2-10 per cent. solutions of silver protein used. Should the cornea ulcerate, atropine drops should be employed and oculent hydrarg. oxid. applied. Eye bandages are undesirable.

Stomatitis usually subsides quickly; the mouth should be cleansed with a lotion containing chlorate of potash (10 grains to 1 fl. ounce). In the presence of ulceration due to Vincent's organism, neoarsphenamine should be injected or applied locally. The supervention of noma calls for bacteriological examination and antitoxin or surgical interference in the way of cauterisation or free excision. Enterocolitis is managed on the same lines as infantile epidemic diarrhoea.

Convulsions and encephalo-myelitis are treated by sedatives and lumbar puncture, repeated if the cerebro-spinal fluid is under increased pressure. Intramuscular, intravenous or intrathecal injection of 10 c.c. of blood serum from a recently recovered case with this complication, if obtainable, seems worthy of a trial.

Sulphonamides are useful in the prophylaxis as well as treatment of secondary broncho-pneumonia and of middle-ear diseases.

In an uncomplicated case of measles the patient may be allowed up 2 or 3 days after the temperature subsides. Supervision should be exercised during the convalescence of severe cases, and the possibility of later tuberculosis borne in mind. Ear discharges call for skilled treatment, as they may become chronic (see also directions on p. 79).

RUBELLA

Synonyms.—German Measles, R  theln.

Rubella is quite distinct from ordinary measles and from scarlet fever. It protects only against itself. Amongst the exanthemata it is distinguished by its long incubation period, its short invasive stage, its characteristic adenitis, its benign course and the time of its seasonal prevalence.

  tiology.—The infectivity is less than that of measles and of short duration. Like measles it is infectious for a day or two before the eruption appears. Infection is facilitated by close contact and there is no evidence that the disease is spread by fomites. Infection through an intermediary cannot be considered proved. The infective agent is unknown, but a filtrable virus has been suspected.

Rubella is prevalent in the first half of the year. Cases increase from January to a maximum in May and June. After that an abrupt fall ensues. A series of local outbreaks usually occurs, determined by the aggregation of a number of unprotected young adults. A more or less pronounced epidemic wave occurs every third or fourth year. The maximum incidence is at a later age period than that of measles, but even the youngest infants have been known to take the disease. Its frequency much diminishes after the age of 30. Sex is without influence, but the occurrence of rubella in pregnancy is said by some to favour the incidence of cataract and other congenital malformations.

Symptoms.—The incubation period, although variously stated to be from 7 to 22 days, is usually 17 or 18 days.

Premonitory symptoms are mild or altogether absent, but a short catarrhal stage usually occurs, the rash making its appearance within 24 hours. Rarely a longer prodromal period of ill-defined febrile illness occurs before the eruption. The characteristic adenitis of the mastoid, occipital, cervical or other lymph glands can, more often than not, be detected for a day or two, exceptionally even a week or longer, before the appearance of the rash.

The rash has two stages. Macular, slightly papular and morbilliform in its progress, it frequently fuses and becomes scarlatiniform in its second stage. Discrete spots first appear on the face or neck; they invade the circum-oral region and may be found behind the ears and on the scalp. Sometimes they are first found on the wrists, chest, shoulders, or even on the legs. They are smaller than the papules of measles, pale pink in colour, and tend to cluster in small groups. The rash quickly extends to the trunk and limbs and in most cases as quickly fades. On the second day the face is no longer spotty but appears diffusely erythematous ("sunburnt"). Sometimes the outbreak of the eruption is halting in its progress. The scarlatiniform stage is not developed in all attacks; it is due to the fusion of the discrete elements, and is generally best marked on the trunk, especially so on the back. It becomes most apparent on the second day of the eruption. The rash rarely lasts more than 72 hours and hardly stains the skin, thus contrasting with measles.

The mucous membrane of the cheeks is not inflamed, and Koplik's spots never occur. The tonsils may be slightly swollen and reddened, sometimes a follicular exudate is present. Some degree of pharyngeal catarrh is evident, and the tongue may be lightly coated. A fine vesiculation and congestion

of the soft palate are often seen, and the orifices of Stenson's ducts may be vividly injected. The gums may be injected and tender. The conjunctivæ are pink and the eyes slightly suffused. Photophobia is rare. Fever is slight, even when the rash is intense. Often there is no fever at all. The pulse and respiration rates are only increased in proportion to the febrile disturbance.

A tender adenitis is very distinctive. The mastoid and occipital glands may rapidly attain the size of peas; the posterior cervical glands are also enlarged, frequently too those in the axillæ and groins. The enlarged glands are firm, tender and discrete; suppuration never occurs. As a rule resolution takes place rapidly when the rash subsides. The urine presents no special characteristics.

As in the case of morbilli, a polymorpho-nuclear leucocytosis occurs during the incubation period, but a leucopenia with a relative increase of lymphocytes is found in the eruptive stage. More distinctive is a high percentage of plasma cells and Türk cells in the first week of the attack.

Convalescence is remarkable speedy. Slight furfuraceous desquamation may occur.

Complications.—Complications and sequelæ are as a rule non-existent. When they do occur they are trivial and take the form of mild recurrent sore throat, slight laryngitis, or bronchial catarrh, rheumatism, or transient albuminuria. In some outbreaks benign polyarthritis has been a feature. Otitis is very rare, and meningeal symptoms, encephalo-myelitis, or polyneuritis, rarer still.

On occasions, epidemics of rubella of more severe type, approximating in symptoms and sequelæ much more closely to measles, have been described.

Diagnosis.—The disease has a similarity to measles and scarlet fever, especially when the latter occurs in a mild form. In addition, the rash of rubella must be distinguished from toxic and drug rashes, from the eruption of secondary syphilis, from glandular fever, and from certain skin diseases.

Measles is differentiated by the following points. The incubation period is shorter, being 14 days from exposure to the appearance of the rash; cough and catarrhal symptoms are marked, the mucous membrane of the mouth is inflamed and Koplik's spots are present. The rash appears later, is darker, more persistent, and stains. There is no late scarlatiniform stage. Fever is more pronounced, prostration more evident, and the mastoid and occipital glands are not especially enlarged. Pulmonary complications are much more likely to occur.

Rubella is often mistaken for scarlet fever. Distinctive points in favour of the latter are: the short incubation period; the occurrence of such initial symptoms as vomiting, marked faucial inflammation, shivering or severe headache. The fever is high at onset and the pulse disproportionately rapid. The circumoral region is free from rash, and by the fourth day the tongue has peeled. The occurrence of such sequelæ as arthritis, cervical adenitis and nephritis, also typical pinhole or lamellar desquamation, will clinch the diagnosis. Even in the scarlatiniform stage of rubella, discrete measly elements may generally be detected about the edges of the rash on the forearms, wrists, legs and ankles. An eruptive fever which simulates measles at its onset and scarlet fever later, is generally rubella. Occasionally glandular fever (*q.v.*) resembles rubella.

Toxic, enema and drug rashes may bear a resemblance to the rash of rubella, but as a rule these rashes are very irregular in their distribution and polymorphic in character. The characteristic tender local glandular enlargement and slight catarrh of rubella are absent.

Of skin diseases, erythema scarlatiniforme and pityriasis rosea are sometimes mistaken for rubella. The first named bears a greater resemblance to scarlet fever; unlike rubella, it avoids the face, does not give rise to swelling of the mastoid and occipital glands, and shows a great tendency to recur.

Pityriasis rosea, itself possibly an infective fever, is distinguished by a herald patch which precedes the general eruption, and the fact that the latter usually appears first on the upper part of the trunk. The rash often shows commingled macular and ringed lesions. The patches are slightly scaly and are decidedly larger and more persistent than the papules of rubella. There is no catarrh and no conspicuous glandular enlargement about the head. The patches desquamate in a characteristic manner from their centres, which are fawn coloured, towards the margins, which are slightly elevated, darker and ringed by a collarette of scales.

Secondary syphilides bear a superficial resemblance to the rash of rubella, but are distinguished by the presence of a primary sore, the characteristic throat and the conspicuous increase in size, and shottiness of the glands in the vicinity of the chancre. The Wassermann reaction is of value.

The Paul-Bunnell reaction will distinguish glandular fever.

Prognosis.—Recovery is the rule; second attacks are known, but not common, and relapse is very rare.

Treatment.—PROPHYLACTIC.—As the incubation period is long a quarantine of 3 weeks is theoretically necessary for contacts, but is rarely imposed. They may be watched or isolated from the tenth to the twenty-first day from exposure to infection. Early warning of the imminence of attack may be gained by carefully watching the mastoid and occipital glands.

CURATIVE.—The patient should be isolated and kept in bed until all symptoms have subsided. In 7 days all infectivity has ceased, provided there is no persistence of faucial, nasal, respiratory or other symptoms.

SMALL-POX

Synonym.—Variola.

Definition.—An acute, specific, highly infectious fever, characterised by a definite incubation period and a distinctively distributed, deep-seated eruption which passes through the stages of papule, vesicle, pustule and crust. A pre-eruptive, toxic or septicæmic, and an eruptive or focal phase are recognised. The fever-chart reflects these phases—a remission at the outbreak of the rash is followed by a reaccession on the onset of the pustular stage.

Ætiology.—All races, both sexes, and persons of every age are susceptible if unprotected by a previous attack, or by efficient vaccination. This general liability is most evident when the disease is introduced for the first time into a new community; under such conditions it may decimate the population. Its present-day incidence on adults is accounted for by vaccination in infancy; in endemic centres it was, prior to the introduction of vaccination, a disease of early childhood. For centuries endemic in Asia small-pox has at times

been epidemic in every civilised country, following trade routes and the channels of communication. It is more severe in hot climates, but always its virulence has varied greatly in different localities and different outbreaks. Coloured races take it badly. Unlike scarlet fever and measles, it frequently attacks infants at the breast. When small-pox occurs during pregnancy, the disease in the mother tends to assume a confluent or hæmorrhagic type and infection of the foetus is common but not inevitable. Abortion or premature delivery is to be expected in all severe attacks. The foetus contracts the disease in utero, usually during the pre-eruptive (septicæmic) stage in the mother, the incubation period being shortened. Sometimes foetal infection is delayed and may even only occur at the time of separation of the placenta. Few of the children born in these circumstances survive, sometimes they show the rash or its scars at birth.

In England and temperate climes most outbreaks occur during the winter and spring, and tend to die out with the commencement of summer. Small-pox protects against itself, and second attacks are rare. Vaccination gives complete immunity for some years and partial immunity usually persists afterwards. Complete natural immunity is very rare, but is reported. Inoculated small-pox affords more complete immunity than vaccination.

Infection with small-pox is, almost certainly, through the respiratory tract, and may be direct or indirect, *i.e.* by contact, which need not be very close, with a patient suffering from the disease or through the medium of objects infected by the sick person. Intermediaries may carry the contagium in their clothing or in their hair. The greater incidence in the neighbourhood of small-pox hospitals suggests the possibility of aerial convection of the virus for considerable distances, perhaps exceeding a mile, but the influence of human carriers in these cases is hard to eliminate. Bedding, clothing and rags may retain their infectivity for considerable periods of time, especially when stored. Transmission by flies and domestic animals is regarded as a possibility. The infectivity of small-pox is slight at the time of the symptoms of onset, and is much greater when the eruption appears. The infectivity in the early stages is, by some, attributed to primary and unrecognised lesions in the respiratory tract. It continues until all the scabs have separated. The virus is very resistant to desiccation and long persists in the dry scales and crusts shed from the body. Corpses of those recently dead from small-pox can transmit the disease. Tramps are often responsible for the conveyance of infection from one locality to another.

There can be no doubt that small-pox is due to a living virus. Minute, but characteristic, intracellular bodies are found in the epithelial cells of the pocks of small-pox and vaccinia, and also in the cornea of the rabbit, after scarification with the virus of these diseases. They are known as *Guarnieri bodies* and are aggregations of the "elementary bodies" of Paschen. The elementary bodies of small-pox and of variola minor are agglutinated by the sera of patients convalescent from either form of the disease.

Pathology.—The cutaneous lesion of small-pox lies in the deeper layers of the epidermis. Vesiculation is due to serous exudation between the cells. Loculation is caused by vertical strands of the ruptured epithelial cells which radiate from the base of the pock. The tenseness of the vesicle and tethering of the covering by this reticulum cause the pock to be umbilicated. In malignant attacks, where the pocks are

flaccid, and in the old and debilitated where a similar condition may obtain, umbilication is often absent. With pustulation the fibres of the reticulum are destroyed and the pock becomes dome-shaped. The suppuration is attributed to secondary infection with *streptococci* or with *staphylococcus aureus*. On mucous membranes the vesicles rupture almost as soon as formed and are rapidly converted into shallow erosions. The chief blood change is an initial leucopenia, followed after the first week by a leucoeytosis in which mononuclear cells preponderate. A secondary anæmia may become pronounced.

The post-mortem appearances are those usually found in acute infective processes. The rash persists, the liver is often much enlarged, the spleen swollen, and the lungs broncho-pneumonic. Particular attention has been drawn to the presence of local necroses in the liver, testicles and bone marrow. These are often infiltrated with mononuclear basophil cells. In hæmorrhagic small-pox, petechial and purpuric hæmorrhages are found in the skin, mucous membranes, lungs and other viscera, sometimes also in the retro-peritoneal tissues and the roots of the mesenterics.

Symptoms.—*Unmodified small-pox; Variola major.*

Period of incubation.—Taking the first symptoms of invasion, this is from 10 to 14 days. The average period is 12, or counting to the appearance of the rash, 14 days. Extremes of 5 to 23 days are mentioned but are rare. With increasing virulence the incubation period tends to shorten. In inoculated small-pox the generalised eruption appears on the eighth to the eleventh day.

Period of invasion—Toxic or septicæmic stage.—In a typical unmodified attack the invasive symptoms are sudden and of great intensity. The most prominent are severe chills or rigors, marked pyrexia, severe frontal headache and intense pain across the loins. The temperature quickly reaches a maximum of 103° to 104° F., and is accompanied by severe prostration. Vomiting may occur, particularly in children. Delirium, mental symptoms and even suicidal tendencies may accompany this stage. With these severe symptoms are coupled more ordinary febrile manifestations, such as anorexia, thirst, coated tongue and disturbed sleep. The breath is offensive, the skin usually hot and dry but sometimes perspiring, and the bowels constipated. There are, however, mild attacks in which the symptoms of invasion are much less severe, and even in more severe attacks pain across the loins is by no means constant. Mild invasive symptoms usually presage a mild course; with a severe invasion the attack is generally, although not invariably, grave.

Prodromal rashes belong to the toxic or septicæmic stage, and may precede the proper eruption for 1 or 2 days, but they are not always present. There are two types, one purely erythematous, the other petechial or hæmorrhagic with or without accompanying erythema. The pure erythemas are of a bright red or dusky purplish colour and may appear on the trunk, where they are often patchy and evanescent, or be limited to the bony prominences and extensor surfaces of the limbs. They may suggest the rash of scarlet fever or bear a superficial resemblance to that of measles. The hæmorrhagic or petechial rash, which often has at first a dusky erythematous background, is more characteristic. It appears in the groins, which are stippled with small petechiæ; invades the thighs for an inch or two and extends in an ill-defined manner on to the abdomen (*bathing drawers rash*). Sometimes it extends towards the axillæ and may be found on the back of the neck and flexures of the knees. The petechial rashes are persistent and indicate a severe attack.

The erythemas are fugitive and of good prognostic import ; the only exception is a very brilliant universal œdematous erythema of face, trunk and limbs known as the *astacoid* or lobster rash which sometimes ushers in hæmorrhagic small-pox. Later this may be replaced by livid sheets of deep subcutaneous hæmorrhage.

Eruptive or focal stage.—Distribution.—On the third day the invasion is at its height and the focal eruption appears. This is not necessarily profuse, indeed in mild and modified attacks it may be limited to a few lesions on the distal parts of the limbs and on the face. Whether scanty or profuse, the rash is centrifugal in distribution, appearing first on the forehead near the scalp, and on the temples, then on the backs of the wrists and hands, and a day later about the ankles and feet. Its extension is rapid and symmetrical and its elements deeply seated in the skin, uniform in size and more or less circular. In marked contrast to the prodromal petechial rash it is least profuse on the abdomen and groins, scanty on the chest, more evident on the back, especially across the shoulders, increasing as it descends the arms to thicken on the extensor aspects of the wrists and hands. Most profuse of all is the outbreak on the supraorbital, malar and nasal prominences of the face. The rash reaches the lower extremities within 24 hours and here is most evident about the ankles and feet, where it may still be in the papular stage whilst that on the face has become vesicular. Meantime the lesions multiply on the parts already affected, the eruption becoming thick on the face and perhaps on the scalp whilst still scanty on the parts involved later. In 3 days it will have attained its full density and typical distribution, but the earliest lesions will be in a more advanced stage of development. It is highly characteristic of the eruption of small-pox to avoid depressions, flexures and protected flexor surfaces such as the armpits, groins, flanks, orbital hollows, supraclavicular hollows and flexor aspects of the toes. Abnormal irritation by bands of clothing, irritants, scratching or exposure to sun and weather may determine a profuse eruption on areas where, ordinarily, pocks are scanty. The pocks, too, tend to aggregate along prominent bones and tendons but may strangely avoid the prominences formed by the clavicles and the malleoli.

Maturation.—On its *first* day the rash consists of small dull-red *macules*. Within 24 hours these become *papules* which feel shotty when pinched up between the finger and thumb, the hardness being best appreciated by pinching a fold of skin between the fingers on the face, hands or forearms. On the *third* day many papules have become *vesicles*, but vesiculation may be recognised on the summits of the papules at an even earlier stage. By the fourth or fifth day the eruption is completely vesicular and the toxæmic symptoms and fever of onset may have subsided. The vesicles, circular in outline, slowly increase in size and become surrounded by red areolæ. They are now the size of split peas, greyish, and set in rather than on the skin. Umbilication is evident and loculation is proved by failure to collapse when transfixed by a sterile needle. The contents of the vesicles remain clear for 24 hours only ; they then become purulent, so that by the *fifth* day *pustules* are evident on the face and by the eighth day are universal. With pustulation, the pocks soften, become flat-topped and lose their areolæ. Reaccession of fever with constitutional symptoms and often delirium, the *secondary suppurative fever*, accompanies the process of suppuration or maturation. A marked inflammatory œdema of the skin may now appear, causing the features to

become swollen and expressionless and impeding the movements of the hands and fingers. Much tenderness and itching may accompany this œdema. Suppuration destroys the loculation of the vesicles and also obliterates umbilication. Adjacent lesions, particularly on the face and hands, may run together in the vesicular and pustular or even the papular stage—a process which produces the *confluent rash*, a sign of severe infection. On the *ninth* and *tenth* day the pustules begin to *desiccate*, some first rupture or are torn by scratching, and collapse. Brown or black crusts result which separate by the end of the thirteenth or fourteenth day, but where the skin is very thick, as on the palms and soles, the dried-up unruptured pustules may form deep-seated “seeds” which may take weeks to work their way to the surface.

To summarise : the rash is papular on its first and second days ; vesicular on the third and fourth ; pustular on the fifth and sixth and thereafter desiccating. A rash which remains papular after the third day or is fully vesicular by the second day is unlikely to prove to be due to small-pox.

The cutaneous eruption is accompanied by an outcrop of greyish infiltrations on the conjunctivæ and mucous membranes of the mouth, tongue, nose and pharynx. In severe cases the larynx, bronchi, gullet and even the stomach may also be affected. On the mucous membranes infiltrations and vesicles are soon transformed into shallow grey ulcers. Vesication may be observed on the palate, whilst the lesions are still indeterminate on the skin. In consequence of the eruption the eyelids, fauces and tongue become sore, the nose is obstructed and deglutition is painful. Implication of the larynx will cause hoarseness or aphonia and even dangerous œdema. The mucous membranes of the vulva, vagina and rectum do not escape.

A mild generalised superficial adenitis is common.

The fever (Fig. 6) of invasion reaches its acme with the appearance of the rash, then it falls, but not immediately. It is generally normal by the fifth day of the attack, often before this. It is at this stage, in the milder attacks with scanty rash, the patient may attempt to resume his ordinary occupation, and, in modified cases, very little further febrile disturbance may ensue. Ordinarily, however, the secondary suppurative fever now sets in and reaches its acme about the ninth or tenth day of the disease. Its duration in the more severe cases is from 10 days to a fortnight. In severe and confluent small-pox the remission of temperature in the vesicular stage may be absent.

The pulse and respirations are quickened proportionally to the degree of fever present, but in grave attacks the respirations become more rapid, shallow and irregular, and the pulse accelerated and feeble. In malignant and hæmorrhagic infections death may occur from toxæmia within the first week. In the gravest cases a subnormal temperature accompanies the toxic stage and death may result from circulatory failure, even within 24 hours, the mind remaining clear.

The urine is febrile in character. Some albumin may be present, and a diazo-reaction may be obtained.

Owing to the depth of the lesions in the skin, depressed scars are left, the amount of pitting depending on the degree of suppuration. The pits show a reddish staining which may persist for months. Some desquamation may accompany the separation of the crusts, particularly on the feet and hands. The hair often falls out freely. The nails may be shed. Convalescence is, in favourable cases, rapid and complete.

VARIETIES.—Small-pox may assume severe, modified or benign forms:

Severe types of small-pox.—In addition to malignant or severely toxic attacks these include the confluent and the hæmorrhagic varieties. *Confluent small-pox* is characterised by fusion of the lesions, particularly on the face and hands. The rash may fuse whilst still papular, but more commonly does so in the vesicular and pustular stages. In such cases the toxæmia is severe and the remission of symptoms before the stage of pustulation may be absent or ill-marked. Delirium is common, and the secondary fever high. Inflammatory cedema is very marked, the features may become quite unrecognisable and the confluent pocks may form a continuous sheet of pus. Severe conjunctivitis, nasal obstruction, salivation, cough, aphonia and diarrhoea are common. Some patients pass into a typhoid condition.

FIG. 6.—Confluent small-pox in an unvaccinated adult.

An offensive odour emanates from the body, circulatory failure is progressive, and death may occur towards the end of the second week.

Hæmorrhagic small-pox.—In the most malignant variety (*Purpura variolosa*), the incubation period may not exceed 7 or 8 days. Purpuric flecks and patches may appear in the skin before the development of the eruption, but spots of greyish infiltration may already be appearing in the buccal and palatine mucosa and rapidly become confluent. The cutaneous hæmorrhages are accompanied by subconjunctival hæmorrhages, hæmaturia and bleeding from the mucous membranes. Initial symptoms, in particular backache and prostration, are severe, and prodromal rashes common. The respiration is hurried and the breath sickeningly foetid, but the temperature not necessarily very high. Death may occur before the outbreak of the proper eruption gives a clue to the nature of the infection, but often towards the end careful inspection may detect a few papular elements of the focal rash.

In other cases the bleeding manifests itself later, and accompanies the eruption, in the form of petechiæ or of circular spots between the lesions and infiltrations of their bases staining their contents. The pocks are often

badly developed, confluent and of a violaceous hue (*variola hæmorrhagica pustulosa*). Bruises form easily in the skin, and hæmaturia, epistaxis, hæmatemesis or uterine hæmorrhage may add to the gravity of the outlook.

The mere presence of blood-stained contents in the vesicles, especially those on the legs, without hæmorrhages into the bases of the poeks, or in the intervening skin and elsewhere, is not of bad prognostic importance.

Modified small-pox or varioloid.—Small-pox of a mild type may occur in vaccinated subjects. In some such, initial symptoms may be slight, and the eruption, although typical, is precocious and scanty. More commonly, the initial symptoms are severe, but again the rash appears early, is generally sparse and discrete, tends to evolve quickly, and many of its elements fail to progress beyond the papular or vesicular stage. The suppurative fever is slight or absent. The lesions of modified small-pox are often small, superficial and may be unilocular, sometimes they appear fleshy and wart-like. The modification is most evident on the face. In such cases the lack of depth and the arrest of maturation leading to the juxtaposition of papules, vesicles and small pustules may cause a resemblance to chicken-pox, or suggest measles complicated by chicken-pox, but the distribution remains characteristic.

Rarely small-pox aborts completely in its initial stage, the focal rash failing to appear (*variola sine variolis*). The subjects of this form of the disease have usually, but not invariably, been vaccinated at some previous time.

Variola minor.—From time to time a benign type of small-pox has prevailed in many parts of the world. The names *alastrim*, *amaas*, *varioloid*, *varicella* and *para-variola* also designate this disease. It differs from ordinary small-pox in its mild course, low mortality (0.5 to 2 per cent.), lesser infectivity, the mildness or absence of secondary fever, the occurrence of residual pigmentation rather than pitting, and incidence on adults rather than on children.

The incubation period is 10 to 15 days, or longer. Invasion is abrupt, and may be accompanied by muscular pains, backache, vomiting and sometimes high fever, although many cases are ambulatory. The rash usually appears on the fourth or fifth day. It is seen first on the face, then on the forearms and trunk, and within 12 hours on the lower limbs. The eruption may be scanty or moderately profuse. It rarely comes out in crops, but in any case the initial lesions are more advanced than those which follow. Maturation is more rapid than in *variola major*, papular and vesicular stages each lasting 2 days, pustulation beginning early, and scabbing on the face being evident within a week. There is, as a rule, no secondary fever, but its absence is not invariable.

The distribution of the eruption is classical, the rash favouring the face and extremities rather than the trunk. On the limbs, the distal parts, and on the trunk the upper part of the back, rather than the abdomen and chest, are involved. Much weight is attributed to the detection of a few deep-seated lesions in the skin of the thenar and hypothenar eminences.

The lesions are more superficial than in *variola major*, but not so superficial as the vesicles of chicken-pox. They are not always spherical, and are often unilocular and not umbilicated. Mature vesicles have an opalescent rather than frankly purulent appearance, and the crusts are of a deep amber colour. It is easy to understand why the disease is so often mistaken for

chicken-pox. The distribution of the rash is the important diagnostic criterion. Although vaccination protects against *v. minor* the converse is not invariably true. As a rule, vaccination in the eruptive stage fails, but may take in modified form later.

Although serological tests fail to differentiate *variola minor* from *variola major*, histological examination shows that the inclusion bodies of *v. minor* show differences in numbers, size, staining reactions and localisation in the vesicles when compared with *v. major*.

Complications.—During the later stages of small-pox and in convalescence boils and superficial abscesses often cause trouble. Septic rashes and erysipelatous or impetiginous infections may spread from the pocks. The cervical and axillary glands may in such cases become enlarged or even suppurate. In the more severe infections, deep-seated muscular abscesses, cellulitis or sloughing of the skin may occur and bed-sores may form rapidly over pressure points. Rarely death is due to septicæmia arising from these secondary lesions.

Ocular complications are important. Conjunctivitis is common. Pustules may form on the palpebral or ocular conjunctivæ. The eyelids often become inflamed and cedematous. A rapidly spreading keratitis may lead to sloughing of the cornea, but corneal ulcers are more common and sometimes lead to perforation and panophthalmitis. Iritis is rare. Retinal hæmorrhages sometimes cause blindness. The scars of the corneal ulcers may impair the sight.

Otitis media is comparatively common.

Laryngeal inflammation may be so severe as to necessitate tracheotomy, and may lead to perichondritis and necrosis. Bronchitis and bronchopneumonia are frequent and often accelerate death, but lobar pneumonia and purulent pleurisy are rare. Endocarditis and pericarditis are also exceptional, but degenerative changes in the myocardium are not infrequent. Occasionally a destructive arthritis supervenes; it is said to be more common in childhood. Although albuminuria is often found, a true nephritis is uncommon.

Parotitis is looked upon as a secondary duct infection from the mouth, and secondary orchitis sometimes occurs during the acute stage.

As in other fevers encephalo-myelitis and neuritis may occur some 5 to 13 days after the appearance of the rash, but the incidence of these is exceedingly low. On recovery from the toxæmic stage speech may be completely lost, but it returns. Less favourable are bulbar or limb paralysis, with or without derangement of sphincter control (see p. 1605).

Deep pitting of the face, permanent blindness, deafness and sometimes alopecia may be the legacies of a severe attack.

Diagnosis.—Papular or vesicular rashes which even though scanty affect the face and extremities symmetrically are always suspect. The body should be stripped and examined in a good light. A preliminary bath may be needful. Attention is first focused on the distribution rather than on the characters of the rash. The individual lesions should be plotted on an outline diagram of the body, and a numerical comparison made of those on the abdomen, chest, back, shoulders and upper arms, forearms, face, thighs and legs. Too much reliance should not be placed on shottiness or umbilication. The condition as to vaccination should be ascertained and the nature of any prevailing epidemic borne in mind.

The initial fever may itself lead to difficulty in diagnosis; the symptoms of onset are very similar to those met with in other acute diseases, particularly influenza, acute rheumatism, pneumonia and cerebro-spinal fever. Severe prostration and backache, when present, are suggestive. Often the diagnosis is not certain until the focal eruption appears on the third day and the fever subsides, but the appearance of a petechial prodromal rash in the groins may enable earlier recognition. As regards influenza, it is more common for small-pox to be mistaken for this disease than for the converse to occur. Lumbar puncture is diagnostic in cerebro-spinal fever. In pneumonia sooner or later lung signs appear. Precipitate certification of a supposed case of small-pox, even in a contact, is unwise; it is better to await the appearance of the rash, remembering this should appear first on the forehead, near the roots of the hair, the cheek bones, sides of the nose, wrists, hands and forearms. The interior of the mouth should also be inspected and any parts of the skin which have been subjected to special irritation.

The prodromal rashes, if purpuric, may be confused with different varieties of purpura or leukaemia; if erythematous, with scarlet fever, measles, rubella, urticaria or other forms of erythema.

The characteristic groin or "bathing drawers" incidence of the purpuric rash of small-pox is of great assistance in early diagnosis. More widespread purpuric rashes, however, are at times misdiagnosed as febrile purpura until the occurrence of small-pox in contacts reveals their true nature. Conversely, febrile purpura and purpuric rashes occurring in ulcerative endocarditis, cerebro-spinal fever and other conditions may be mistakenly thought to indicate small-pox. The distribution of the rash and the character of accompanying symptoms should be noted. Physical examination of the organs may reveal signs which help to clear up the diagnosis, which may be very difficult.

A scarlatiniform prodromal rash is distinguished from scarlet fever by the absence of tonsillitis and of punctate redness of the soft palate. The rash too on the skin is not definitely punctate and the area of circumoral pallor is wanting. The tongue is not typical nor are the tonsillar lymph glands enlarged. The Schultz-Charlton test is negative.

Morbilliform prodromal rashes bear only a very superficial resemblance to measles. The diagnosis is discussed below. Nor should rubella be confused if its characters are borne in mind. The prodromal erythemas may resemble those induced by antitoxic serum, by soap enemas and by drugs. The characters of these rashes are given in the article on scarlet fever (p. 76).

The focal eruption of small-pox may be confused with measles, chicken-pox, perhaps typhoid or typhus, also with various forms of papular erythema, urticaria, acne, papular or pustular syphilides, and glanders. Sometimes drug rashes, particularly those due to iodides, lead to mistakes. Confluent or hæmorrhagic small-pox in the papular stage is often mistaken for measles. The three-day prodromal fever and lesions in the mucous membrane of the mouth favour this error. But there is no real catarrh in small-pox, and the buccal infiltrations only superficially resemble Koplik's spots. The distribution of the rash on the body, and the fact the temperature tends to fall as the eruption increases instead of rising as it does in measles are distinctive.

The differentiation of some cases of chicken-pox is a difficulty. Chicken-pox is a disease of childhood whilst small-pox chiefly affects adults (although

with neglect of vaccination its incidence in childhood may again increase), but cases of chicken-pox in the adult are not infrequent, and in them prodromal symptoms may be sharp and the rash not appear until the second or third day. Chicken-pox presents the following distinctive characters :

1. The rash of chicken-pox appears first on the trunk, and is thickest on the trunk, face, upper arms and thighs. It is centripetal and tends to avoid the extremities of the limbs. It does not so markedly select irritated areas, nor does it avoid the axillæ and groins. The presence of many lesions on the palms and soles is greatly against chicken-pox.

2. The eruption comes out in distinct crops for 3 to 5 days or more.

3. The vesicles develop much more rapidly and are mature in 24 hours. Vesicles are not seen at this period in small-pox.

4. The lesions are superficial and unilobular, rarely umbilicated. Their bases are not indurated. Near flexures they may assume an oval outline, sometimes becoming irregular or crenated.

5. The outbreak of fresh vesicles on a given area of skin over a period of 24 to 72 hours is characteristic. Hence by the third day the lesions of chicken-pox are in various stages of development from vesicles to crusts.

6. The lesions are smaller. Pustules and scabs half an inch across are almost certainly due to small-pox.

7. Efficient vaccination within 5 years or revaccination within 10 years is generally but not invariably evidence against the disease being small-pox.

8. Chicken-pox does not protect against successful vaccination in an unprotected individual : in small-pox vaccination will not take after the rash has appeared. This rule, however, is not absolute. Vaccination may prove successful in anomalous forms of small-pox, and has been alleged to take in ordinary small-pox on rare occasions.

9. Apathy and muscular relaxation are not features of chicken-pox. A copious rash with complete absence of prostration suggests chicken-pox rather than small-pox.

Confusion with typhoid and typhus is uncommon, and should be avoided by taking into consideration the distribution of the rash and character of the other symptoms. In distinguishing other skin eruptions it should be remembered that erythemas are often polymorphic. They may show occasional vesiculation which is quite superficial and are sometimes febrile. Acne affects the face, shoulders, back and chest ; it is chronic, afebrile, and often associated with comedones and scars. The lesions may be pustular but are never vesicular. The lesions are not found on the forearms or hands.

If syphilis is borne in mind its eruptions are not likely to be mistaken. Reliance must be placed upon their distribution, colour, polymorphic character, other signs of syphilis, the history and the Wassermann reaction, but a patient with syphilis may also have small-pox. Glanders is rare, but when the nodules on the face suppurate and are accompanied by fever, small-pox may be suggested. There is usually a nasal discharge and a history of association with horses. Bacteriological examination will show the *Bacillus mallei*.

Laboratory diagnosis.—Certain laboratory tests have been elaborated for the detection of small-pox :

1. Complement deviation, flocculation and precipitation tests can be applied, using, with necessary changes, the vesicular fluid, the crusts or the convalescent serum of small-pox, or immune serum of vaccinia.

2. Paul's test depends on the production of Guarnieri bodies by scarification of the cornea of a rabbit with vesicular fluid from small-pox or vaccinia.

3. The intradermal injection of vesicular fluid produces in the rabbit a characteristic inflammation which is prevented by previous admixture with hyperimmune rabbit serum.

4. The procedure recommended by van Rooyen and Illingworth who have shown that even in the early papular as well as in the vesicular stage of small-pox the elementary bodies can be demonstrated in great profusion by the application of Paschen's method of staining to films of scrapings from the bases of the buccal lesions, the skin papules and the vesicles, but not the pustules of small-pox. This facilitates early diagnosis. Moreover, since the elementary bodies of chicken-pox are smaller, scantier and extremely difficult to stain, the important differentiation of the two diseases is possible.

Prognosis.—Natural small-pox has a mortality which varies from 25 to even 50 per cent. The prognosis may be considered under the following heads: (1) The vaccinal condition of the patient; (2) the age; (3) the nature of the attack; and (4) the character of the prevailing epidemic.

1. When a vaccinated person takes small-pox the nature of the attack usually indicates some residual immunity, the severity of the disease being less and the mortality much lower than in the unvaccinated. The presence of large, well-foveated vaccination scars renders the prognosis very favourable. After the age of 15 or even 3 years earlier, the protective influence of infantile vaccination will to a large extent have disappeared, but revaccination at puberty, properly performed, confers a high degree of immunity for the rest of life.

2. In the unvaccinated the death-rate in the first 5 years of life is very high and may exceed 40 per cent. After that there is a fall, at first gradual, then considerable, up to the age of 15 or 20, which is the most favourable period. Subsequently the mortality rises steadily and may even exceed the figures given for the first quinquennium. In the vaccinated, however, the younger the patient the more certain is recovery. If revaccination has not been performed, as age increases the mortality does so also, and may reach 15 per cent. in persons over 30 years of age.

3. The nature of the symptoms is important. Mild invasion presages a mild attack. Severe invasive symptoms usually, but not invariably, mean a severe infection, but they may precede mild attacks in the vaccinated and sometimes in others. Prodromal rashes of a vivid lobster hue, especially if petechiæ are present, are the heralds of grave, often hæmorrhagic infections. Very intense backache is also an ominous invasive symptom. The more profuse the pustular rash the worse the prognosis, but the intensity of the suppurative stage is much modified by previous vaccination. Confluent eruptions mean a bad outlook, whilst patients in whom the rash remains discrete usually recover. Recovery from the vesicular or pustular form of hæmorrhagic small-pox is occasional, but in the early *purpura variolosa* death is usually inevitable. Bleeding from mucous membranes is of very bad augury.

Other unfavourable symptoms are incomplete remission between the primary and secondary fever, sleeplessness, active delirium, especially in drinkers, considerable implication of the larynx and broncho-pneumonia. The influence of pregnancy in inducing abortion and miscarriage has already been mentioned.

4. Epidemics vary much in their severity and mortality. In some the disease is so slight and the mortality so low, that doubts arise whether the epidemic is really small-pox.

Treatment.—**PROPHYLACTIC.**—Vaccination and revaccination are the most powerful safeguards. The chief measures to be taken when the disease is recognised are the following: (1) Prompt removal of the patient to an isolation hospital. (2) Thorough disinfection of infected rooms and clothing. (3) Immediate and efficient vaccination or revaccination of all other members of the household and of contacts. Four or even more days after exposure vaccination may prove effectual in preventing the disease, at all events will modify it (see p. 171). (4) Quarantining of contacts for 16 days, or a daily inspection so that initial symptoms may be detected at once. (5) Notification of schools or institutions attended by inmates of the same house.

Inoculation with small-pox, which prior to vaccination was a method of prophylaxis, is said in some instances to have a mortality of 2 or 3 per cent.; but even this compares favourably with a mortality of 40 or 50 per cent. as seen in some epidemics of ordinary small-pox. Inoculation, however, was found to spread the disease, and so has, in England, been made a penal offence.

SYMPTOMATIC.—Fresh air, cool surroundings, light bedclothes, free fluid intake, regulation of the bowels, and tepid sponging night and morning form the regular routine. The mouth should be cleansed regularly, and the nose gently douched or liquid paraffin instilled. Pain in the head and back may be mitigated by the ice-bag to the scalp and use of fomentations to the loins. Aspirin, phenacetin, or chloral and bromide may give relief; but the drug most generally useful, both in this stage and in the sleeplessness, delirium and discomfort of the secondary fever, is opium in the form of 10 grains of Dover's powder. Sometimes paraldehyde is effectual. Delirious patients should never be left alone. The vomiting of the early stage is allayed by citrating the milk or substituting ice and champagne. Liquor iodi mitis in 5-minum doses is also useful. When fever continues high and is accompanied by toxæmia and delirium, tepid sponging may be replaced by hot or cold packs with advantage. Many methods have been tried of aborting the eruption and preventing the subsequent sepsis and pitting. Sulphonamides have no influence on the toxic stage, but both sulphanilamide and sulphathiazole are said to influence favourably the focal eruption in the vesicular stage and to be of value in the septic complications. Some advocate painting the face with liquor iodi mitis, diluted if painful, twice a day for the first 8 or 10 days, and then applying soft paraffin; or, better, commencing in the papular stage, a saturated (5 per cent.) solution of potassium permanganate may be painted over the whole body three times a day until scabbing begins, and afterwards less frequently. In confluent cases the patient may be immersed daily in a 3 per cent. permanganate bath for 15 minutes at body temperature. The application of a lint mask soaked in glycerin is useful, and glycerin may also be applied to the hands, or a dilute carbolic compress substituted. It may be necessary to cut the hair short. To mitigate the offensive odour, dilute carbolic lotions may be applied (they also relieve the itching), or creosote may be vaporised in the sick-room. Starch poultices and alkaline washes are used for the removal of crusts and zinc ointment or a 5 per cent. sulphathiazole ointment with 1 per cent. of phenol applied. The eyes should be bathed with boric

acid lotion at frequent intervals, and dilute nitrate of mercury ointment smeared on the edges of the lids. Should keratitis threaten, silver protein is instilled or an ointment of atropine with yellow oxide of mercury applied.

Laryngitis calls for a steam tent and inhalations of benzoil or lysol. Circulatory failure is combated by strychnine with adrenaline injections or other circulatory stimulants.

Patients are to be regarded as infectious until the scabs are all separated and the skin and mucous membranes quite healed.

VACCINIA

Vaccinia or cow-pox, a disease at one time very prevalent among cows, but now rare, is characterised by a vesicular eruption on the udders and teats. The vesicles, which are surrounded by inflammatory areolæ, may by rupture form extensive ulcers. Abrasions on the hands of milkers may be accidentally inoculated from these lesions and they, in turn, may inoculate other cows in the herd. The hands of the infected milker show vesicles with surrounding induration, the axillary glands become swollen and there is some fever. Individuals thus inoculated are protected from small-pox, and Edward Jenner made practical use of this fact by inculcating the practice of deliberate vaccination and transference of the virus from arm to arm. In addition he demonstrated that those thus vaccinated were refractory to subsequent inoculation with the virus from small-pox lesions, and milkers who had had small-pox did not catch vaccinia from the cows. But it appears that although vaccinia protects against small-pox, an attack of small-pox does not always protect against vaccinia. Apparently vaccinia is the more powerful antigen.

After long dispute, the question of the identity of cow-pox and small-pox has been settled by animal experiment in favour of Jenner's view that the two diseases are one and the same, small-pox virus being so modified by its transmission through the cow that its inoculation results only in a local lesion, a lesion which, however, affords a high degree of protection against small-pox. Vaccinia differs from small-pox, whether the latter be natural or deliberately inoculated, in that it has lost its infective character, and so can be used for purposes of vaccination without risk of propagating small-pox.

The histology of the vaccine vesicle is similar to that of the lesion of small-pox. It goes through the stages of papule, vesicle and pustule; and loculation is produced by persistence of the remnants of vacuolated epithelial cells in the form of septa.

Professor Paschen has described minute "elementary bodies" as constant accompaniments of vaccinal lesions, and Ledingham has shown that these "Paschen bodies" are agglutinated by the sera of rabbits which have recovered from vaccinia. It is believed that these bodies are the filtrable virus of the disease.

For the purpose of vaccination vaccine lymph is prepared by the inoculation of healthy calves, the contents of the vesicles being collected and freed from pyogenic and other extraneous organisms by admixture with glycerine. This process of glycerinisation kills most of the adventitious germs, but leaves the virus of vaccinia uninjured. The lymph thus prepared, if stored in

capillary tubes at low temperature, will remain efficacious for at least 8 months. Its use is preferable to the direct inoculation from human vaccine vesicles practised in arm-to-arm vaccination.

The operation of vaccination is carried out as follows : An area of skin over the insertion of the left deltoid muscle or on the outer side of the thigh or leg is carefully cleaned with soap and water, and afterwards with ether. The contents of a tube of lymph are then ejected on to the cleansed area in 2, 3 or 4 separate portions, according to the number of insertions proposed. A $\frac{1}{2}$ inch scratch is made through each drop of lymph with a sterile lancet or sterile needle, care being taken to avoid drawing blood, and the lymph gently rubbed over the scratches with the instrument used. The scarified spots should be at least an inch distant from each other to avoid confluence. The lymph is given a few minutes for absorption, and any excess is removed with sterile wool. The scarified area is covered with sterile gauze. The whole procedure must be carried out with strict regard to asepsis. "Cross-hatching" is avoided but two parallel half-inch scratches are more effective.

If the operation is successful, inflamed areas appear at the sites of inoculation, and by the third day become distinctly papular. By the fifth day, small clear vesicles have formed which slowly increase in size and become depressed at their centres. By the eighth day the vesicles are large, sharply defined, and their inflammatory areolæ are confluent. From this time the contents become increasingly cloudy. The vesicles attain their full size by the twelfth day and collapse. By the tenth or twelfth day a brownish scab is forming. This separates later, leaving a depressed and pitted or foveated scar which at first is livid, but in course of time becomes dull white.

Vaccine virus has now been propagated by tissue culture and a more recent method of vaccination is by subcutaneous or intracutaneous injection of diluted vaccine. At present it is difficult to appraise its value.

The virus is distributed by the blood throughout the body. Headache, malaise and fever accompany maturation of the vesicles at the beginning of the second week; the axillary glands may become enlarged and tender and the spleen palpable. Sometimes febrile disturbance is noticed as early as the fourth day.

In revaccination the events are similar, but both the local and constitutional disturbances are less pronounced or may fail to appear. The lesions may run a very rapid course, aborting at the papular or early vesicular stage. The time taken for maturation of the pocks is inversely proportional to the degree of immunity present (*Cory's law*). A papular reaction within 8-72 hours may merely indicate sensitivity, not partial immunity.

Natural insusceptibility to primary vaccination is excessively rare, and at least three successive attempts should be made before insusceptibility is assumed.

Although infants can be vaccinated successfully in the first few weeks of life, under ordinary circumstances the best period is from the second to the sixth month. Revaccination is advisable after the seventh year and when small-pox is epidemic.

The degree of protection afforded against small-pox is in some degree proportional to the extent of the vaccinal lesion, and the resulting scars should, together, cover an area of not less than half a square inch. Hence the advice

always to make at least two insertions and preferably four. The test of a successful scar is its depression and foveation. The period of immunity may be regarded as not less than 7 years. When vaccinal encephalo-myelitis is prevalent, vaccination by one insertion has been recommended, but evidence of its efficiency is not convincing.

RISKS OF VACCINATION.—Fugitive erythemata, which are sometimes scarlatiniform, measly or urticarial, may appear about a week after vaccination; they are akin to serum rashes. Erysipelas, septic infection and cellulitis sometimes result from the use of contaminated lymph or the lack of proper cleanliness at the operation or after. Under modern methods of glycerinisation and asepsis, these should not occur. There is no doubt, too, that syphilis has on rare occasions been conveyed by arm-to-arm vaccination. In such cases, the chancre does not appear before the fifteenth day, and is usually later. The calf being insusceptible to syphilis, the use of calf lymph has abolished this danger. Tetanus is another infection which has occasionally resulted, especially in hot climates. Tuberculosis and leprosy have also been cited as possible sequels, but with little or no proof. The addition of glycerine to the lymph kills the tubercle bacilli. The appearance of eczema and impetigo has been attributed to vaccination, as also a somewhat persistent form of anaemia.

A rare sequel, to which attention has been drawn recently, is a form of encephalo-myelitis. Its greatest incidence has been in Holland, Great Britain and Germany, and has varied from 1 in 5000 to 1 in 100,000 vaccinations. The characteristic lesion is a focal, perivascular demyelination of nerve fibres, often associated with perivascular cuffing. It very rarely follows vaccination during the first year of life. Its chief incidence is after primary vaccination of children of school age or of adolescents. Very similar to the encephalo-myelitis of small-pox and of measles, it sets in 7 to 12 days after vaccination, with headache, vomiting and paresis. These symptoms become aggravated, and delirium may pass into coma and death. In other cases the symptoms are more suggestive of meningitis, myelitis, lethargic encephalitis, with ocular palsies or tetanus. The mortality may reach 50 per cent., but complete recovery is possible. Human serum, from a healthy donor who has been successfully vaccinated recently, or anti-vaccinal horse-serum, is the best antidote. The serum is given intrathecally or intravenously. The dose is 8–30 c.c., repeated if necessary. Repeated lumbar puncture is a valuable adjuvant.

Quiescent infection may be brought into activity and prominence by vaccination; this is the case with congenital syphilis and tuberculosis. Hence the advisability of postponing vaccination should the infant show signs of ill-health. Acute specific fevers are no bar to vaccination if necessary.

Very rarely the course of vaccinia is complicated by the appearance of a generalised vesicular eruption, the lesions appearing in successive crops, and passing through the stages of papule, umbilicated vesicle and crust. Generalised vaccinia of this type is usually febrile and occurs from 7 to 11 days after vaccination.

Accidental vaccinia is the term applied to fortuitous inoculation from a vaccinal lesion. Mothers are sometimes thus inoculated from their infants. The possibility should be borne in mind. When occurring on the face, there is much oedema with swelling of the lymph glands, so that anthrax has been

suspected. The vaccinated baby may also, by scratching, inoculate its own nose, cheeks, fingers or other parts of its body.

PROTECTION AFFORDED BY VACCINATION.—The immunity to small-pox which vaccination confers is not necessarily permanent. Ten years is considered an average duration. A child vaccinated in infancy should be revaccinated at the age of 7 years and again in adult life. Whatever their vaccinal condition, with the possible exception of those vaccinated within 2 years, persons coming into contact with small-pox should be revaccinated at once.

Since vaccinia has a shorter incubation period than small-pox, a person efficiently vaccinated or revaccinated within 3 days of exposure to the latter disease will, in all probability, escape it. Ricketts makes the following statement: "The period of incubation of small-pox, counting to the outcrop of the rash, may be taken as 14 days. If this period be divided into three intervals comprising 7 days, 3 days and 4 days, it will be accurate, in the main, to say that a successful vaccination done in the first period will wholly prevent the attack, done in the second will have more or less effect in modifying the eruption, and done in the third will merely add to the patient's troubles."

For a discussion of the evidence in favour of the practice of vaccination in the prevention of small-pox, the student is referred to the larger treatises.

CHICKEN-POX

Synonyms.—Varicella; Glass-pock; Water-pock.

Definition.—An acute infective disease, characterised by a rash which tends to appear in successive crops, each lesion passing rapidly through a papular stage to one of superficial vesiculation and subsequent partial pustulation. The lesions then desiccate and scab.

Ætiology.—Chicken-pox is universally prevalent and highly infectious. One attack usually affords complete protection, second attacks being extremely rare. It is mainly an affection of middle childhood, being uncommon after 10 years of age, but adults even of advanced years may contract it, and infants are not completely immune. Season and climate are not known to exert any influence on its incidence. It affects both sexes. Infection is in most cases direct by droplet spray, but articles of clothing may remain infectious for a considerable time, and the disease is sometimes carried by a healthy intermediary. The dried scabs can communicate the disease, probably by powdering and ingestion or inhalation. Like small-pox, chicken-pox is inoculable from the vesicles—but not easily. Convalescents from acute diseases, particularly from measles, diphtheria and scarlet fever, are believed to be peculiarly susceptible to chicken-pox. The disease occurs sporadically or in the form of limited outbreaks. The infective agent is a virus, and the association with herpes zoster lends support to the view that it may be a filtrable virus, identical with the neurotropic virus of that disease.

Pathology.—Micro-organisms occur in the pocks, and particulate bodies have been described similar to those seen in vaccinia and small-pox. Pure suspensions of these particulate or elementary bodies are agglutinated by the serum of convalescents from varicella or herpes zoster. The inflammatory lesions are more superficially situated in the skin than those of small-pox; but the process of vesiculation is similar. Loculation is indistinct, and umbilication exceptional. When the clear vesicles become clouded, but

rarely before this, polynuclear and mononuclear cells are found in their contents.

Symptoms.—*Incubation period.*—This is usually a fortnight or a little more; but extremes of 11 to 23 days are mentioned.

In childhood the appearance of the eruption usually constitutes the first sign, and is taken to indicate the first day of the disease. In adults slight pyrexia and sometimes headache, shivering, and even pain in the back may precede the eruption for 48 hours. In exceptional cases, mostly in children, vomiting and convulsions have occurred.

Prodromal rashes are not very uncommon. An erythema, either patchy or uniform, which may be punctate, sometimes precedes the eruption for some hours, and may be mistaken for scarlet fever; it avoids the face, does not blanch by the Schultz-Charlton test, and does not desquamate. The incipient papules of chicken-pox can sometimes be recognised in the erythema. Less frequently the prodromal rashes are measly or urticarial.

The eruption of chicken-pox appears first on the trunk, but soon spreads to the face, the scalp and the proximal parts of the limbs. Sometimes it is on the face that it is first noticed. Occasionally, and sometimes primarily, the eruption invades the mucous membranes, especially the fauces, soft palate and the pharynx. The spread of the rash does not conform to the orderly progress of small-pox, it appears in several crops on successive days; these may come out for 2 or 3 days in mild cases, for a week or more in those which are severe. The total number of lesions may be anything from a few to some hundreds. They are thickest on the trunk, especially on the back, and next to this on the face and in the scalp. They tend to invade the limbs from above downwards, being sparse and often small on the distal portions; a few vesicles are occasionally seen on the palms and soles. The axilla does not escape as in small-pox, and it is unusual for the rash to show an especial incidence over ridges or pressure points. Various forms of skin irritation may determine a local profusion of the rash.

The lesions are in turn macular, papular, vesicular and mildly pustular. The macules are very transitory, soon becoming rounded or ovoid papules of a pinkish colour and slightly salient, something like the rose spots of typhoid, or larger. Vesiculation rapidly ensues, and is complete in 24 hours or a little more. The vesicles seldom exceed a third of an inch in diameter. They look like translucent droplets, lying on rather than in the skin. An areola may or may not be present. On the scalp, forearms, hands and feet they may appear deeper, and show some hardness. Some assume oval or irregular outlines, especially when lying near creases or folds of the skin. On maturity the vesicles take on a pearly hue. When punctured, most of them collapse entirely, and umbilication is rare. Confluence of adjacent vesicles hardly ever occurs. Owing to its itchiness, the rash is often infected by scratching or rubbing, and then the lesions become larger and more inflamed. Otherwise the vesicles dry up into superficial brown scabs in a day or two, which on separating leave slight pink stains, but no appreciable pitting.

The appearance of the eruption in successive crops leads, as the disease progresses, to the presence at the same time on a given area of skin of lesions in all stages of development, i.e. papules, vesicles, small pustules and scabs. On mucous membranes the vesicles soon rupture and leave shallow grey ulcers, often with red areolæ.

Slight pyrexia usually accompanies the appearance of the rash. Some cases are apyrexial throughout. Rarely the temperature rises as high as 103° or 104° F. Successive crops of spots may be accompanied by successive recurrences of fever. Constitutional symptoms as a rule are absent.

Varieties.—Chicken-pox varies much in intensity. It may be so mild that only one or two pocks are recognised. As mentioned above, sharp invasive symptoms may mark its advent in the adult. There are three special varieties of the severe disease: (1) *Varicella bullosa*; (2) *Varicella gangrenosa*; and (3) *Varicella hæmorrhagica*. In *V. bullosa* the vesicles rapidly form large blebs, which on rupture leave painful raw surfaces. *V. gangrenosa* is seen in debilitated children and those recovering from scarlet fever; large dark crusts form, and on separation reveal ulcers which may spread on the surface and in depth with great rapidity. Constitutional disturbance is severe, and pulmonary complications often supervene. Infection of the lesions with yellow staphylococci, hæmolytic streptococci or virulent strains of the diphtheria bacillus should be suspected. *V. hæmorrhagica* is rare; hæmorrhages occur into the vesicles and intervening skin, and bleeding sets in from the mucous membranes. It is very fatal. Bleeding confined to the vesicles is not so serious.

Complications.—Laryngitis or slight bronchitis is present in some cases. Pocks on the conjunctivæ, vulva or prepuce may give rise to troublesome symptoms. Accidental septic infections sometimes occur in the eruptive stage. Acute nephritis and arthritis are exceptional results of these.

Nervous complications are very rare and usually benign. They are attributed to encephalo-myelitis, and chiefly affect children, usually occurring during the second week of the infection. Rarely they precede the eruption. The onset is acute and febrile; it may be accompanied by vomiting, vertigo and convulsion. Ataxia and tremor are more common than motor paralysis. With spinal lesions the picture may be that of a transverse myelitis. Optic neuritis, ophthalmoplegia and, very rarely, peripheral neuritis have also been recorded. In most cases recovery has ensued.

Herpes zoster is closely akin to chicken-pox. A scattered vesicular rash indistinguishable from chicken-pox may precede, accompany or follow the zoster eruption. Herpes zoster may also give rise in contacts, mostly children, to typical chicken-pox after an incubation period of from 12 to 21 days, and chicken-pox may follow inoculations from zoster vesicles. Conversely, for chicken-pox to give rise to herpes zoster, is a much less common event, which usually occurs in adults. It is a curious fact that there is no evidence of any cross-protection between the two diseases.

Diagnosis.—A mild or modified case of small-pox may erroneously be supposed to be chicken-pox, or chicken-pox with a profuse eruption and constitutional, or the rare hæmorrhagic, symptoms may be supposed to be small-pox. The differential diagnosis, in which the distribution of the rash is of primary importance, is considered in the article on small-pox. Here it may be stated that in a patient under 10 years of age, with well-foveated vaccination scars, a profuse eruption is generally chicken-pox, whilst a scanty eruption with well-marked invasive symptoms is more likely in these circumstances to be modified small-pox.

The erythematous prodromal rash may simulate scarlet fever; but

other signs of this disease are wanting, and the chicken-pox eruption appears within 24 hours. (See also p. 172.)

Certain skin diseases characterised by vesicles or bullæ may be mistaken for chicken-pox. These include insect bites, scabies, acne, impetigo, papular urticaria, pemphigus and erythema multiforme. Differential criteria are prolonged duration, recurrences, distribution, absence of fever, and no lesions in the mouth.

A varicella-like type of syphilide is known. It usually affects the trunk, is much more persistent, and is accompanied by other evidence of its nature.

Prognosis.—Death is very rare. The gangrenous form may prove fatal to debilitated children, and the rare hæmorrhagic form is said by most authorities to have a very bad prognosis.

Treatment.—Although most infectious in the pre-eruptive and early eruptive stages, patients should be isolated until every scab has separated—usually a period of 2 or 3 weeks. They should be confined to bed during the eruptive period. Skin irritation may be allayed by mild dusting powders, and it is sometimes advisable to fix the arms in light splints. It is rarely necessary to cut off the hair. Inflamed pocks may need fomentation with boric acid. Crusts which re-form may be removed by starch poultices and zinc or mercurial ointment applied. Septic or gangrenous varicella may be treated by the use of scarlatinal or diphtheria anti-toxin, and drugs of the sulphonamide group internally, or in the form of 5 per cent. sulphathiazole ointment with 1 per cent. phenol.

When discharging patients particular attention should be paid to the scalp, as scabs may remain entangled in the hair. It is doubtful if lesions which have crusted several times are still infectious. The quarantine period for contacts is 3 weeks, but it is quite safe for it to commence 10 days after exposure to infection and be maintained for 12 days.

Attempts at prophylaxis with convalescent serum have not proved very successful—10 to 15 c.c. from a convalescent within a month of an attack is given intramuscularly.

MUMPS

Synonyms.—Epidemic Parotitis; Infectious Parotitis.

Definition.—An acute infectious disease, characterised by swelling of the parotid, and sometimes of the other salivary glands, accompanied by constitutional disturbance which is usually mild. With the exception of orchitis, complications are infrequent, and a fatal termination is exceedingly rare.

Ætiology.—Mumps is endemic in most large centres of population throughout the civilised world. No climate is adverse and no race is immune. Children and young adults of both sexes are those usually attacked; but no age is entirely exempt, although the disease is rare in infants and in the aged. The mother has transmitted the disease to the fetus *in utero*. Dogs and cats have been known to contract the infection from their owners.

The malady usually appears during the winter or spring months. Outbreaks are generally localised, and often limited to particular schools, business houses or barracks. Infection is direct from patient to patient; but is sometimes conveyed by an apparently healthy intermediary, or by fomites. Epidemics of mumps may follow outbreaks of measles.

Pathology.—Mumps is attributed to infection by a neurotropic filterable virus. Invasion of the nervous system is thought by some to occur prior to invasion of the salivary glands. An alternative view is that a primary septicæmia is followed by localisation of the virus in certain susceptible organs. The disease can be passed to cats and monkeys by bacteria-free filtrates of saliva or puncture fluid from the swollen glands, and has been re-transferred from monkey to man. Older views were that certain diplococci or spirochætes were the infecting agents.

An interstitial inflammation is said to occur in the affected salivary glands, but parenchymatous inflammation is described in the case of the pancreas and the testicle.

Symptoms.—The incubation period is 3 weeks; but extremes of 14 and 35 days, or even 37 days, are admitted. A swelling of the parotid gland is usually the first indication of the malady, but this may be preceded for a day or two by pain and stiffness in the region of the masseter muscle, or by such prodromal symptoms as feverishness, shivering, and sore throat. Sometimes a meningeal reaction marks the onset (*Cerebral Mumps*).

The parotid swelling is at first unilateral, and commonly appears on the left side. It may increase for 2 or 3 days, forming an ill-defined, elastic swelling, which obliterates the sulcus between the mandible and the mastoid process, lifts the auricle away from the head in a characteristic manner, and extends forwards on the surface of the masseter. Only rarely is the skin over and around the gland either reddened or cedematous. The swelling subsides after a few days, sometimes very quickly, but a distinctive and, when present, highly diagnostic feature is the occurrence, 24 or 36 hours after onset, of swelling in the other parotid region, sometimes with fresh febrile disturbance; or the submandibular and sublingual glands may now be attacked. The interval between the invasion of the two parotid glands may extend to 4 or 5 days, or even longer; sometimes they are attacked simultaneously. Sometimes, too, the submandibular glands become swollen first, in which case palpation with one finger in the mouth and another below the jaw will reveal the acorn-like swelling. The parotid may escape, or may swell in its turn. When multiple bilateral glandular swellings are present the features become much distorted.

Moderate pyrexia (101° or 102° F.) may accompany the onset and persist for a day or two; but the attack is often afebrile and the pulse rate hardly quickened. On rare occasions constitutional disturbance is severe, the temperature rising to 104° or 105° F., with delirium and circulatory depression.

The glandular swellings are accompanied by a feeling of tension rather than acute pain, but the inflamed parotid gland may cause great pain on attempts to separate the teeth, to chew or to swallow. The secretion of saliva is often defective, but in some excessive salivation is noticeable and food may increase the swelling of the gland. Injection of the orifices of the salivary ducts, pharyngitis, and even tonsillitis are sometimes observed at the height of the attack. Enlargement of the cervical lymph glands rarely occurs. Mumps may appear in so mild a form as to be hardly noticeable. At times the only gland affected is the submandibular (*submaxillary mumps*). Occasionally orchitis or pancreatitis is the sole manifestation of the disease. Invasion of the lachrymal gland has occurred in some instances.

With rare exceptions the swellings caused by mumps neither suppurate nor persist, although, occasionally, the parotid gland is said to be several months in resolving. Relapse occasionally occurs.

During the period of glandular swelling the blood usually shows a moderate leucocytosis, a characteristic feature being a relative and absolute increase in the number of lymphocytes. The supervention of orchitis does not invariably alter the blood picture, although, according to some authorities, it may give rise to an increase in the number of polymorphonuclear cells.

Complications.—*Orchitis* occurs in 15 to 30 per cent. of the males. It affects boys about the age of puberty and young adults; in childhood it is rare. Sexual activity is held to be a definite predisposing factor. The seventh or eighth day of illness is the usual time of onset; but it may appear 2 or 3 weeks later. In some instances orchitis precedes the inflammation of the salivary glands. The condition is really an epididymo-orchitis. Where surgical attempts have been made to relieve tension by decapsulation or incision, effusion has been found in the tunica vaginalis, the testis engorged, and the epididymis deep red. The onset is characterised by pain in the testis, which soon becomes swollen. Delirium, vomiting, collapse and considerable fever may accompany the testicular inflammation. The temperature may rise abruptly to 103° or 104° F. Fortunately the complication is usually one-sided, but in 10 to 20 per cent. of cases the other testicle is attacked in turn. Orchitis may be accompanied by œdema of the scrotum, swelling of the spermatic cord and enlargement of the inguinal glands. Exceptionally urethritis accompanies the testicular swelling. Subsidence of orchitis within a week is the rule, the temperature falling rather abruptly. Suppuration is very rare; but relapse sometimes occurs. When bilateral orchitis occurs before puberty the development of the individual is usually checked; rarely feminism has been reported. In the adult, even when both testes appear atrophic, spermatogenesis may return after many months.

In the female, ovaritis, inflammation and œdema of the vulva and mastitis are occasional complications.

Pancreatitis is a much less common complication than orchitis, but like the latter on rare occasions is the only manifestation of mumps. It should be suspected when acute abdominal pain, fever, vomiting and epigastric tenderness occur as sequels to the parotid swelling, which under these circumstances may show a rapid subsidence. Sometimes the swollen pancreas may be felt, but often its presence is masked by abdominal rigidity. The bowels are constipated, the stools may be fatty, or even contain blood. The serum and the urinary diastase is increased, and glycosuria may occur. The blood sugar may be raised. Jaundice is rare. The onset may be accompanied by alarming collapse. Fortunately recovery has occurred in most cases. Diabetes as a sequel to mumps is very exceptional, but undoubtedly may occur, sometimes even when the abdominal symptoms have been quite trivial. It should be noted that in mumps a raised diastatic index may occur without clinical evidence of pancreatitis, and is attributed to infection of salivary glands.

As regards the *nervous system*, symptoms of meningo-encephalitis may set in towards the end of the first or during the second week, and have even been known to precede the appearance of the glandular swellings. Sometimes on recovery such disabilities as aphasia, hemiplegia, monoplegia or ataxia persist. Rarely a general paralysis of the limbs with loss of deep

reflexes, attributed to peripheral neuritis, occurs. Weakness of the muscles supplied by one facial nerve very rarely accompanies the parotid swelling.

Acute mania and other forms of insanity are unusual sequels.

An excess of lymphocytes may be found in the cerebro-spinal fluid; and is not uncommon during the first fifteen days of mumps, even in the absence of definite meningeal symptoms.

Certain affections of the *organs of special sense*, although uncommon, deserve mention on account of their importance. Quite apart from deafness, due to the occasional occurrence of otitis media, true nerve deafness may occur unaccompanied by signs of middle ear disease. The deafness is of sudden onset, and when accompanied by nausea, vomiting, tinnitus and inco-ordination it is attributed to hæmorrhage or exudation within the labyrinth; but it may occur without any labyrinthine symptoms. Fortunately the deafness is usually unilateral, for it is incurable.

Papilloedema and optic atrophy with loss of vision are other rare but important sequels. Iridocyclitis; paralysis of certain extra-ocular muscles and loss of power of accommodation may also at times ensue; these mainly terminate in recovery after a variable time.

Among other possible complications may be mentioned epistaxis; bronchitis, pneumonia; pericarditis and arthritis. Albuminuria is not uncommon and nephritis sometimes occurs as late as 4 or 5 weeks after the onset of the salivary swellings; uræmia has been responsible for death in rare instances. Gangrenous appendicitis has also been noted.

Suppuration in the parotid gland, gangrene of the gland, cellulitis of the neck and floor of the mouth, cedema of the glottis, and suppuration of the cervical lymph glands are very rare events, which are generally attributed to superadded septic infection.

Relapses, characterised by a recurrence of the glandular swelling after a distinct interval, are not very uncommon. Although one attack of mumps usually protects the individual for life, second attacks are not unknown.

Diagnosis.—In the presence of an epidemic this presents little or no difficulty; but the true nature of the infection may be overlooked in sporadic cases or when the parotid swelling is insignificant, and when the disease primarily affects the submandibular or sublingual glands, or again when orchitis or even pancreatitis constitutes the first, and perhaps the only, manifestation.

Parotitis, usually unilateral, and attributed to ascending duct infection, is a well-known complication of certain fevers, and of some abdominal diseases; but it may also occur in a primary and recurrent form. This is distinguished from mumps by the circumstances under which it occurs, and by the fact that it is not contagious. It generally ends in suppuration, and is accompanied by a polynuclear leucocytosis. Swelling of the salivary glands may also follow the administration of certain drugs, such as iodide of potassium and pilocarpine.

A painless enlargement of the parotid and lachrymal glands, of great chronicity, occurs in Mikulicz's disease. In uveo-parotid fever irido-cyclitis accompanies the parotid swelling (see p. 561).

Inflammatory swelling of the higher cervical glands, especially when accompanied by peri-adenitis and cedema, may be mistaken for mumps. Swelling of this character occurs in certain cases of malignant diphtheria, and also in

scarlet fever. Careful attention to the history, proper examination of the fauces, and search for rashes should eliminate this error. Enlargement of the pre-auricular lymph gland due to lesions about the nostrils and angle of the mouth, and the swelling caused by periostitis of the lower jaw, or otitic infection of a zygomatic air-cell, may superficially resemble inflammation of the parotid, as also in some cases may subcutaneous emphysema.

When the submandibular and sublingual glands alone are swollen the distinction from lymphadenitis may be difficult. In such cases extension to the opposite side indicates mumps, as also does the transitory character of the swelling. In all forms of septic adenitis a polynuclear lymphocytosis is likely to be present.

In glandular fever, which is an acute infective adenitis of the cervical and other lymphatic glands, the salivary glands are not involved.

Prognosis.—The mortality from mumps is remarkably low. The majority of deaths occur in children under 5, especially in infants, usually from some complication. Attacks of mumps in pregnancy have been known to prove fatal.

Treatment.—Mumps is infectious for 2 or 3 days before the swelling appears, and isolation for not less than 2 weeks from the onset is advisable, provided that one clear week has elapsed since the subsidence of the glandular enlargement. Contacts should be removed from exposure and isolated for 28 days, or better, supervised from the fourteenth to the twenty-eighth day, unless they have already had the disease. Thirty c.c. of whole blood, or 15 c.c. of serum of convalescents, if given on first exposure, seems to prevent infection. Attenuated attacks are difficult to produce, but see also remarks under measles (p. 152). On account of the liability to orchitis, it is better to have mumps before puberty than after.

The patient should be isolated and confined to bed. The incidence and severity of orchitis are said to be less in those who are not allowed to get up until the time at which this complication usually appears is past. Foods which need no mastication are indicated during the acute stage. The mouth should be kept clean. Pain may be relieved by local applications and acetylsalicylic acid. The inflamed testicle should be enveloped in cotton-wool and suspended or supported by a small pillow. If pancreatitis is suspected, fomentations may be applied to the abdomen, small doses of opium administered, and the diet strictly restricted to fluids. Delirium and pyrexia are met by sponging, wet-packs or the ice-cap. Hyoscine may become necessary. Repeated lumbar puncture is beneficial in meningo-encephalitis.

CHARLES R. BOX.

INFLUENZA

Definition.—An acute infectious disease of short duration, existing in pandemic and epidemic form, with sporadic outbreaks. It is characterised by sudden onset, pyrexia, headache, pains in the back and limbs, and a tendency to inflammatory complications in the respiratory system.

Ætiology.—Are the protean features of disease which are at present included in our conception of influenza all manifestations of the same *materies morbi*? Are there influenzas rather than influenza? What causative

factors determine the pandemics of the disease during which the case-incidence rises so rapidly and so enormously? What is the association between benign influenzal catarrhs of endemic and sporadic occurrence and the pandemics which decimate whole races of mankind? These are questions which have baffled epidemiologists and bacteriologists for many years, nor did the exceptional opportunities for observation and research afforded by the pandemic of 1918-19 serve entirely to answer them.

We are ignorant of the reasons why a state of relative quiescence in regard to the incidence of the disease—scattered sporadic cases and mild epidemics—suddenly blazes up into a devastating pandemic. We know that when this conflagration arrives the disease becomes very highly infectious in character, that its virulence is enormously increased and that the usual close association with catarrhs and seasons and latitudes and lowered general resistance is no longer observed. Age gives no security at such times; witness both the high case-incidence and high case-mortality in young adults during the pandemic of 1918-19.

A previous attack of the disease gives little or no protection; according to some authorities the reverse is the case.

In the matter of its relation to other catarrhal states the absence of definite criteria makes it impossible to be precise in diagnosis. It is only in the presence of a severe and widespread outbreak that the guide of probability is of assistance in this respect.

Andrewes and his co-workers at the National Institute for Medical Research in 1933 isolated from the nasopharyngeal discharge of influenza patients a virus which is capable of infecting ferrets. When human influenzal garglings are dropped into the noses of ferrets they become ill in 48 hours and the disease has been transferred from the experimental animals to the experimenter. Further, they have shown that patients who have had influenza recently develop antibodies in their blood which kill, or inactivate, the virus. Neutralisation tests with antisera prepared from human strains prove that different serological varieties of the virus exist. Pfeiffer's bacillus is to be regarded as the commonest secondary invader of the infected tissues. Next to Pfeiffer's bacillus, the micro-organisms most commonly found in association with the disease are streptococci of the hæmolytic kind, pneumococci, *M. catarrhalis* and *Staphylococcus aureus*. It seems certain that many of the most serious and fatal cases owe their lethal character to virulent streptococci. Pfeiffer's bacillus occurs in cases of disease quite other than clinical influenza—septic endocarditis, sinusitis and meningitis. The bacillus is of very small size, is Gram-negative in staining reaction, grows with difficulty on ordinary media and has low vitality outside the human body. A special feature seen in regard to it is the fact that, when present in acute cases of influenza, it usually occurs in enormous numbers in the infected tissues and their secretions.

Symptoms.—So far as can be judged the incubation period is, with considerable constancy, something from 24 to 48 hours. A marked feature of the disease is the abruptness of the onset. So abrupt is it at times that the victim is stricken down, as it were, in the street, and, from being quite well he is, within a few hours, prostrated and already suffering the maximum discomforts of the disease. The temperature rises rapidly; there is often a rigor. The chief symptoms are racking headache, intolerable aching

pains in the loins and limbs, dryness and irritable redness of the mouth and fauces, and a distressing dry cough. An erythematous rash is not uncommon.

Although the symptoms are protean, it is customary to describe certain types of case that are frequently met with, dependent largely upon the particular tissues and functions which suffer the chief results of the infection. It is to be noted that different outbreaks of the disease are prone to be characterised by different clinical types, as also by differing degrees of severity.

1. *The febrile type.*—In this variety of the disease the chief features are pyrexia, with associated malaise, headache, pains in the back and limbs and a moderate degree of catarrh of the upper air-passages. In many cases this type differs only from the "common cold" in its more abrupt onset, its higher degree of pyrexia, its disproportionately severe prostration and its relatively "dry" form of catarrh. The eyeballs are often painful, with some conjunctivitis, and the fauces are often red and slightly oedematous. Cough is often present, with few or no associated pulmonary signs. The pyrexia lasts for a variable time, usually 4 to 6 days; the temperature chart may show two peaks in the 24 hours. It is unusual to see the fever prolonged past the eighth day without some focal complication, generally pulmonary. Defervescence is quite frequently by crisis, but this is by no means the rule.

2. *The respiratory type.*—This is the form of the disease which is most prevalent in pandemics, and, when severe, it is the form to which the mortality is chiefly due. Somewhere about the fourth day of the disease it becomes obvious that the catarrhal process is growing troublesome, with more definite involvement of the larynx, trachea and bronchial tract. A dry catarrh of the larynx and trachea, with pain and distressing cough, may constitute the main feature of the disease. In many cases the temperature falls about the third or fourth day, to rise again concurrently with a definite exacerbation and extension of the catarrh. The respiratory involvement does not tend to remain localised as a bronchitis, but involves the lung tissue, leading to a bronchiolitis and, in many cases, an alveolitis also. Then ensue the signs of acute pulmonary congestion which are so characteristic of the disease, and cause so much anxiety for fear of untoward developments. The respiratory manifestations of influenza infection extend from laryngitis and tracheitis through bronchitis to lobular and lobar pneumonia and pleurisy, both "dry" and with serous or purulent effusion. But the dominant feature, rarely absent in any really severe case, is a condition of capillary bronchitis with intense pulmonary congestion. This may be unilateral or bilateral, is more often basal than apical, but is not seldom universal. The physical signs are copious fine râles (crepitation), with impaired vesicular sound, and, less often, impaired percussion tone. This condition may well be termed the essential lesion of the disease, for even when actual consolidation of the lung is present, this is quite often an incident by comparison, and if the patient dies, he dies with the consolidation rather than of it.

Cough is usually a very troublesome symptom in this type of the disease, and is often quite independent of the need to expectorate. The sputa vary considerably. They may be quite absent, even in cases where there is widespread lung congestion. When present they are generally of a kind that corresponds with the nature of the chief lesion, whether tracheitis, bronchitis or pneumonia. Two special kinds of sputa are very typical of influenza,

and they are seen frequently during epidemics. (a) Bright, pink, frothy mucus, sometimes produced in large amount, it may be as much as a pint in 24 hours. This rose-red mucus results from acute inflammatory oedema of the lung. It may be expelled involuntarily during cough and sometimes it spurts from the nostrils. (b) Tenacious mucus, less viscid than in lobar pneumonia, and more copious, differing also in colour which is of several hues—red, brown, saffron and various shades of green, all of these being occasionally present at the same time. Seen in a white earthenware vessel these sputa are very striking and in a high degree diagnostic.

3. *The malignant type*.—This severe and very fatal form is almost confined to pandemic or to epidemic periods. The patient is gravely ill from the onset, or soon after, with intensely toxic symptoms, cyanosis of a peculiar character ("heliotrope cyanosis") and rapid development of heart failure before focal manifestations have time to show themselves—unless it be the presence of copious fine râles of the kind referred to in (2). The duration of this type of case varies from 48 hours up to a week, and no measures of treatment, however prompt, serve to avert the almost certain issue. It is asserted by reliable observers that death may occur even within the first 24 hours from the onset.

4. *The gastro-intestinal type*.—More strictly, perhaps, gastric and intestinal types. These types are less common in pandemics and epidemics than in small endemics and in sporadic cases. The gastric cases are quite common, and some of the milder endemics seem to "breed true" to a remarkable degree in this respect, leading to a very constant clinical picture of an illness with acute, even abrupt, onset, vomiting, marked anorexia, epigastric and umbilical tenderness, and general prostration. Considerable difficulty often arises in diagnosis (see p. 183), even when there are several cases of a similar kind prevalent.

Jaundice of the catarrhal kind is not very uncommon as a complication. Some of the intestinal cases give no less difficulty, and when severe the likeness to typhoid fever is sometimes very close indeed. Tympanites, diarrhoea and enterorrhagia, associated with continued high fever and a leucopenia, may deceive the very elect.

5. *A nervous type* has been described, but it is perhaps more correct to say that a variety of nerve symptoms may arise both during and after the acute infection, rather than that a recognisable clinical picture is produced (see p. 182).

Complications and Sequelæ.—These are both numerous and important. Indeed, if we except the malignant cases and the very severe respiratory cases occurring during pan- and epi-demic periods, it may be said that the importance of the disease lies more in its complications, and perhaps still more in its sequelæ, than in the stage of infection proper. For convenience these disabilities may be grouped as follows:

1. *Respiratory*.—The main extensions of the catarrhal process have been already referred to, as also has the occurrence of pleurisy. Sinusitis may be mentioned here; it is both common and troublesome. Otitis media also occurs. Asthma sometimes appears for the first time in a patient's life after influenza, and the age of the sufferer may be much more advanced than is usual with asthma generally. Pulmonary tuberculosis not seldom shows

itself also for the first time in the same association. The most frequent sequel of all, however, is the maintenance of a state of chronic congestion or bronchiolitis at one base or both bases of the lung. This condition, which may persist for years, ebbing and flowing with the seasons and with the occurrence of intercurrent catarrhal infections, may prove the starting point of bronchiectasis.

2. *Circulatory*.—Perhaps the most serious complication and sequel is referable to the heart. Some degree of dilatation is very common during a severe attack of the respiratory type, and this condition is apt to prolong convalescence in a very tedious fashion. In some cases a bradycardia due to heart block has been observed: the prognosis in this condition is good. But a much more common form of heart disability is that which arises insidiously after the patient begins to resume his usual routine of life. He is the subject of palpitation, præcordial distress and a sense of undue fatigue with slight effort. In women this state of things is complicated often by nervous symptoms, and attacks of breathlessness and a sense of impending collapse are quite common. As there is frequently in addition a considerable degree of true nervous prostration with mental depression it becomes exceedingly difficult to decide to what extent the heart is really affected. Physical signs in these cases are wholly inadequate; quite often they are absent altogether. Although, with care and encouragement, many of these cases get quite well after a time, a large number unfortunately become more or less permanent "heart invalids." It is not clear what is the exact pathology of the "influenzal heart," but it is perhaps near the truth to consider it in the main a toxic myocarditis; though to what degree it is the nervous mechanism, and to what degree the heart muscle, that suffers we cannot say.

Vasomotor troubles are not uncommon and often complicate the heart condition. Phlebitis may occur.

3. *Nervous*.—The most common complication is the intense depression from which the patients so frequently suffer. In a few cases this leads to actual mental instability and, in fewer still, to suicide. The depression may continue for a long time after the acute illness is over. So common a symptom is it that patients themselves often consider the nature of a recent febrile illness to be definitely established as influenza because of this resultant depression. And they are probably in most cases correct. The headache, which is another very constant accompaniment of the illness, may be so severe as to raise the question of meningitis; it quite commonly leads to some delirium in patients whose nervous system is, in health, none too stable.

A true meningitis occurs now and again with *H. Pfeiffer* in the cerebro-spinal fluid and a clinical picture that is unequivocal. Encephalitis and myelitis are described, but here, again, the diagnosis—from epidemic encephalitis—must always be a difficult matter.

Many other nerve conditions are described by authors. Perhaps neuritis, of both single and multiple types, is the most common. One of us (H) has seen a condition indistinguishable from paralysis agitans follow a severe attack, which ended in complete recovery after several months.

Diagnosis.—During pan- and epi-demics the diagnosis is, as a rule, not difficult, especially when the case is very severe. "Filming" the sputa in a case of the respiratory type is a valuable aid to diagnosis. If the highly

characteristic condition of bronchiolitis with copious fine râles referred to on p. 180 be present in a febrile illness with nerve prostration and general toxæmia, the diagnosis is fairly certain.

The gastric and intestinal cases, and especially the latter, present more difficulty than do the respiratory cases. The gastric cases resemble food-poisoning not a little, and appendicitis may require careful consideration in patients with abdominal tenderness, pain and vomiting, of acute onset. From typhoid fever a severe intestinal case with hæmorrhage and enlarged spleen can only be distinguished by absence of agglutination and negative blood culture. A leucopenia is present in both diseases.

The diagnosis of milder cases of influenza, if occurring in sporadic fashion, is frequently a frank admission that it is well to give the patient and his friends a label to his disease. There are so many causes of an acute febrile illness with malaise and slight catarrh that exact diagnosis may not be possible.

A word of warning is perhaps necessary in respect of diseases known to be prevalent coincidentally with outbreaks of influenza. Thus, true pneumococcus pneumonia, whether lobular or lobar, is not infrequently called influenzal when this latter disease is epidemic. Of greater importance is the fact that waves of incidence of influenza and poliomyelitis and encephalitis sometimes concur. If the practitioner's attention is bent only upon the former disease he is apt to put down to it certain serious nerve lesions that really belong to the latter.

Treatment.—**PROPHYLACTIC.**—As we do not know the factors leading to the production of influenza epidemics we do not know how to prevent them. When they arrive we can, to some extent, control them by efficient quarantine, by early diagnosis and notification and by a proper system of hospitalisation, adequate to the peculiar features presented by the disease. In regard to individual prophylaxis it was formerly held that to keep generally "fit" was a good protection against infection. But recent experience does not confirm this view: influenza attacked the strong as well as the weak; indeed, the robust young adult fell a victim by preference, though this may have been partly because he was more open to infection by virtue of the conditions of his life. The age-mortality as well as the age-morbidity during the 1918-19 pandemic seemed to make it clear that some method of specific immunisation is essential before we can hope to protect against infection. The available vaccines for protective inoculation aim at raising resistance against the secondary infections. Regarded in this light they are rational. So far the virus is not available for specific prophylaxis.

CURATIVE.—1. *General Measures.*—With the onset of symptoms the patient is put to bed and is kept there until the temperature has reached normal and has remained there for 48 hours. He is only allowed up if examination of the heart and lungs, and a review of his general condition, reveal nothing abnormal. If the attack has been severe, the patient should be induced to remain in bed for a week after the temperature is normal, because relapses are common, and are often more dangerous than the original attack. This rule of practice should certainly have no exception in the case of patients over 50 years of age.

The largest available room is chosen, and the bed is placed well away from the walls. Blinds, curtains and screens are dispensed with, and the windows

are kept open day and night. The room temperature is kept as near to 60° F. as possible. If the ideal of free ventilation with warmth cannot be secured in the room, then warmth must be sacrificed rather than ventilation. Neglect of fresh air not only seriously prejudices recovery in the event of pulmonary complications, it undoubtedly tends much to induce them. It is probably the most important point in the general treatment.

The diet is confined to warm fluids, given frequently, but easily digested solids are allowed if the stomach tolerates them; efforts at "feeding up" the patient are to be deprecated. Unless the patient is elderly, alcohol is not needed in the early stages of the disease when there are no complications. The bowels are made to act thoroughly by a double dose of the patient's customary aperient. If he has none, he is given $\frac{1}{2}$ -grain doses of calomel every hour for 4 doses, and this is followed by a saline draught. The patient is sponged all over with warm water twice daily.

2. *Drugs.*—There is no drug which acts as a specific. Aspirin and Dover's powder in 10-grain doses may be given together as early as possible and may be repeated once or twice every 6 or 8 hours. This may be followed by a simple diaphoretic mixture. The sulphonamides are only of service when secondary infections are present, and especially when these are of a pulmonary nature.

3. *Treatment of Symptoms.*—If the headache is severe, phenacetin gr. 10 with caffeine gr. 2 may be given 4-hourly for 4 doses. If the stomach gives trouble, and the tongue is foul, sod. bicarb. and sod. sulphocarb., of each gr. 10, with glyc. acid. carbol. min. 10, may be given 6-hourly with the feeds, well diluted. For vomiting, all feeds are reduced to a minimum, or omitted entirely for 48 hours, giving sips of hot water only, with minim doses of liq. iodi mitis in 60 min. of water hourly for 6 or 8 doses, and one pint of normal saline is introduced into the bowel two or three times during the period of starvation.

Distressing and persistent cough is often the most difficult problem. Local applications to the chest are often of service. If the origin of the cough is irritability of the upper-air passages inhalations of tinct. benzoini co. 4 parts, with menthol or eucalyptus 1 part, are useful. Failing this a spray containing chlorbutol (chlorotone) and menthol, 2 per cent. of each in liquid paraffin, may be used to the nose and throat. In the "essential cough" of the disease, syr. cocillanæ co., syr. codcinæ and linet. terp-heroin. co. are of some value. In intractable cases relief may follow syr. chloral min. 30, ammon. brom. grs. 10, with ext. glycyrrhiz. liq. min. 20, etc., in 4-hourly doses for 4 doses.

Insomnia calls for a general review of the whole programme—ventilation, control of pyrexia, posture, food, stimulants, etc. Failing attention to these things, a sedative draught of ammon. brom. grs. 20 and tinct. valern. min. 20 may be tried; if not successful, min. 120 doses of paraldehyde, with tinct. quillaiæ and tinct. aurantii to cover its unpleasant taste. Failing this, again, chloral and bromide may be given, since drugs of the barbitone group are better avoided.

4. *Treatment of more Severe Cases and of Complications.*—(a) *Intensely toxic cases, with hyperpyrexia.*—Attention to good ventilation should be redoubled. The thermometer and not the patient's sensations must be the guide to the amount of bedclothes. "Cradling" is often very useful, as

also is tepid or spirit sponging. In cases in which the temperature is even then resistant, the cold pack should be used and repeated if necessary. Febrifuge drugs are to be avoided in such cases. Stimulants are now advisable to counteract circulatory failure.

(b) *Pulmonary cases*.—Linseed and mustard poultices are of service here, or kaolin poultice, applying these to the most "congested" parts. Volatile stimulants, sedative expectorants and diaphoretics are the most useful drugs: sp. ætheris co., the iodides in small amounts, bromide and chloride of ammonium, tinct. senegæ, tinct. belladonnæ and liq. ammon. acetatis. Ammon. carb. should only be used where sputa are present, and large doses are of doubtful value at any time. Oxygen delivered through a nasal catheter is useful in all severe cases with cyanosis.

(c) *Heart failure*, to be estimated more by the general state of the patient (facies, cyanosis, dyspnœa, delirium, posture) than by pulse-frequency or physical signs, is met by alcohol, strychnine injections, nikethamide (coramine) subcutaneously, and, as a measure supplementary to these, strophanthin $\frac{1}{500}$ grain in 20 minims of sterile saline solution, injected slowly into a vein of the arm and repeated, if indications are still present, in 8 or 12 hours.

(d) The *post-febrile stage*, often a stage of cardiac and nervous exhaustion in severe cases, requires some caution. Strict recumbency should be enjoined, with careful feeding, stimulants and tonics.

FOOT-AND-MOUTH DISEASE

Synonyms.—Aphtha Epizootica ; Epidemic Stomatitis.

Definition.—A contagious disease, due to a virus, communicated from animals to man, characterised by mild pyrexia, swelling and vesiculation of the tongue and buccal mucosa, accompanied, sometimes, by a vesicular eruption on the hands and fingers.

Ætiology.—Man is relatively insusceptible to infection which, however, is of almost world-wide distribution amongst cattle, pigs and sheep. Up to 1872 there were but few reported cases of supposed foot-and-mouth disease in man. In that year a more virulent form appeared in cattle, and human cases were more frequently described. Bussenius and Siegel in 1897 analysed the reports of more than 1500 cases ; the majority are sporadic or occur in small groups.

Three types of virus have been recognised by immunological tests: anti-serum of types O and A (Vallée and Carré) and C (Waldman) has no protective influence against infection by either of the other two types. In cattle the virus enters through the mucosa of the alimentary tract, a septicæmia ensues during which all the secretions and excretions of the body become infective, with subsequent localisation in the specific lesions. The virus can remain active on hair or in soil for a month.

Foot-and-mouth disease is communicated to man: (1) By the consumption of unboiled milk from a cow suffering from the disease. (2) By direct inoculation: from (a) the saliva of infected animals, or (b) milking cows suffering from the specific eruption on the teats or udders. Those affected are for the most part either children, milkers or cowmen.

Symptoms and Course.—The incubation period of foot-and-mouth disease in man appears to be the same as in cattle, namely, 2 to 5 days. Whatever the route of infection the disease sets in with slight headache, a mild grade pyrexia and dryness of the mouth. This state continues for a few days, and is then succeeded by a period of salivation and the development of the characteristic lesions—vesicles upon the lips and tongue, which contain yellowish-white turbid fluid. In 48 hours or so the vesicles rupture with the formation of superficial ulcers having a smooth purplish base. There may be considerable swelling of the tongue and mouth, which, with the pain, renders mastication and swallowing difficult. At the same time a crop of small vesicles may appear around the nails and on the hands; they increase rapidly in size, become pustules and then scabs, which fall off early in the second week. In adults the disease runs a mild course with recovery in from 7 to 10 days. In young children, fed on infected unboiled milk, the condition is prone to be more severe because of the liability to anorexia, gastro-enteritis and diarrhoea.

Treatment.—This is entirely dietetic and symptomatic. A weak solution of permanganate of potash is perhaps the best local application; strong antiseptics, whether to the mouth or to the hands, must not be employed.

PSITTACOSIS

Definition.—An acute infective disease derived from parrots, resembling typhoid fever in its mode of onset and general features, but presenting also signs of an atypical pneumonia.

Ætiology.—The disease is derived from parrots (hence its name), the green Amazonian parrot being usually the source. Grey parrots, however, are not exempt, and love-birds also suffer from it. Infection is usually conveyed direct from a sick parrot to a human being who has been in close contact with the bird, but a parrot dead of the disease is also infectious. It is probable that a healthy parrot can act as a carrier. Infection from one human being to another, although it seems to occur occasionally, is very rare. In 1892, Nocard isolated a bacillus from the bone-marrow of an infected parrot, and named it the *Bacillus psittacosis*; it was afterwards shown, however, that this was identical with the *B. ærtrycke*. In none of the cases in recent outbreaks, however, has there been any evidence of the presence of this bacillus, and it is now proved by the work of Bedson that the infecting organism is a filtrable virus.

Pathology.—The post-mortem appearances are those of a severe septicaemia, with characteristic changes in the lungs. The latter do not present the picture of classical lobar pneumonia or broncho-pneumonia, but of a "peculiar hæmorrhagic vesicular pneumonia, complicated by pulmonary thrombosis and free from bacteria" (Turnbull). In addition, areas of mucopurulent bronchitis and broncho-pneumonia may occur from secondary infection. The gastro-intestinal tract is usually free from severe inflammation.

Symptoms.—The disease usually sets in rather suddenly after an incubation period of probably about 10 days. The rise of temperature is commonly abrupt, and headache is pronounced. Epistaxis sometimes occurs. The patient is generally dull and apathetic, and passes into a condition suggesting

a typhoid infection. The abdomen may be slightly distended, and there may be a little sickness and diarrhoea at the outset. The spleen is not palpable, but in some cases a few rose-spots have been observed which are of a smaller size than the spots in typhoid fever. Pulmonary symptoms may be present from the outset, or appear after the disease has lasted some days. Cough is often frequent and troublesome, but, as a rule, there is little expectoration. Respiration may be rapid, but the pulse-rate remains low. The signs in the lung range from those of a bronchial catarrh up to massive, sometimes very dense, consolidation. Pleuritic signs are very rare. The disease usually lasts from 2 to 3 weeks, and the temperature may fall abruptly. Temporary rises of temperature during convalescence are often observed, and there may even be a complete relapse.

Diagnosis.—Clinically the disease can be suspected on circumstantial evidence. If one has a patient who presents a general resemblance to a case of typhoid or paratyphoid fever, but whose blood does not give the agglutination reactions, who presents also pulmonary symptoms and signs of an atypical sort, and who has also been brought into close contact with a sick parrot or love-bird, then the diagnosis is justified. A deceptive feature in the diagnosis from typhoid, however, is that sometimes the agglutination reaction to the *B. typhosus* is positive. Indeed, a positive agglutination to one strain of typhoid organism occurring early in the disease and in a high degree of dilution is rather suggestive of psittacosis than otherwise. The blood cultures, however, are negative. It may be impossible at the outset to distinguish psittacosis from influenza, but the supervention of pulmonary complications *within the first few days* is in favour of the latter. Bacteriologically the existence of the disease is proved by the presence of a positive complement fixation reaction in the patient's serum.

Prognosis.—The mortality varies considerably in different epidemics, but may perhaps be put at about 1 in 6. Young people usually recover. Severe involvement of the lungs and failure to maintain a relatively slow pulse are unfavourable factors.

Treatment.—There is no specific treatment, and the use of convalescent serum has proved disappointing. Patients should be nursed with the usual precautions adopted in a typhoid case, but need not be further isolated. Special signs and symptoms must be treated as they arise.

PROPHYLAXIS consists in forbidding the importation of infected birds; cages should be kept clean, and the birds should not be fondled. A bird which falls sick should be immediately isolated or destroyed.

HORDER.

A. E. GOW.

YELLOW FEVER

Synonyms.—Febris Flava; Typhus Icteroides; Yellow Jack; Black Vomit; Kendal's Fever; Fièvre Jaune; Fièvre Amarilla.

Definition.—An acute infectious disease of sudden onset, endemic in parts of tropical America and West Africa, characterised typically by pyrexia, vomiting, a slow pulse relative to the temperature, early albuminuria, and a tendency to hæmorrhages and jaundice. It is caused by a filtrable virus

and is transmitted to man by the common domestic mosquito, *Aedes aegypti* (*Stegomyia fasciata*).

Ætiology.—The endemic haunts of yellow fever have been curtailed in recent years by the destruction of its intermediary host. A circle with its centre in the Isthmus of Panama, and embracing the northern parts of South America, the West Indian Islands and the southern parts of North America includes most of the area of its late prevalence in the Western Hemisphere. Unsuspected reservoirs of infection have been found in the Amazon basin and in parts of Columbia, Venezuela and Brazil. The disease is widely endemic in West Africa, while cases occur far in the interior from the coast of Senegal eastward for over 3000 miles, and northward to the Sahara desert and the Sudan. Stokes, Noguchi and Young died when investigating yellow fever, the infection being probably acquired by direct contact with infective blood rather than by the mosquito vector, *Aedes aegypti*. Carroll in 1900 showed that this mosquito would transmit the disease after a period of 12 days, provided it was fed on the blood of a yellow-fever patient during the first three days of fever. Reed and Carroll also found that the injection of 0.1 c.c. of blood from a yellow-fever patient collected during the first three or four days of fever produced the disease, and that the serum after filtration remained infective. *Aedes aegypti* bites in the daytime, and is most aggressive in the early morning. Its domestic habits make it an efficient vector, as the larval stages develop mainly in artificial containers in or near human habitations. Males and females are equally susceptible, and infection in childhood is common. This type of urban and rural yellow fever differs from jungle yellow fever, which is found in or near tropical forests in Brazil, where *Aedes aegypti* is absent. Adult males who work in the jungle are mainly infected. Wild jungle mosquitoes have been found to harbour the virus, but the common vector is not yet known. Monkeys and possibly the hedgehog or other susceptible animals may play an important rôle as reservoir hosts. In 1927 the West African Yellow Fever Commission found that the Rhesus monkey (*Macaca mulatta*) was susceptible, only one out of 30 monkeys surviving. One attack confers lifelong immunity, and 0.1 c.c. of convalescent human serum protects monkeys. The virus, if dried, will keep for months; it penetrates the intact skin of both man and monkeys, but is no longer demonstrable in the blood and viscera after the fourth day.

The diameter of the virus as determined by filtration through collodion membranes lies between 17–28 millimicrons. It possesses two qualities, viscerotropism and neurotropism; when both are present it is known as "pantropic" virus. In 1930 Theiler found that if pantropic virus was inoculated intracerebrally into susceptible mice they developed encephalitis, unless immune serum was simultaneously injected. After repeated passage through the brain of mice the virus lost its viscerotropism or capacity to attack the abdominal and thoracic organs, and was converted into a neurotropic virus with fixed characters. Injection of this virus or of pantropic virus attenuated by tissue culture immunises against yellow fever and is the basis of prophylactic immunisation.

The fact that immune bodies are demonstrable in the blood of yellow fever cases shortly after infection, and persist permanently in recovered cases has been utilised to determine the endemic incidence of the disease. Mice are employed for the purpose. The protection test, as developed by

Sawyer and Lloyd, consists of an intracerebral inoculation of starch solution; followed by the intraperitoneal injection of virus and the serum to be tested. In the absence of immune bodies in the serum the virus produces encephalitis and death within a fortnight; if immune bodies are present the animal remains unaffected. This test has been of great value in affording an index to past epidemics, and in accurately determining the past and present geographical distribution of the disease. Examination of liver specimens obtained by means of the viscerotome from persons dying of illness of not over ten days' duration have also lead to the detection of unsuspected reservoirs of infection.

Pathology.—Death generally occurs between the fifth and ninth day of the disease. Rigor mortis comes on early. The skin may show ecchymoses and is an intense yellow colour, which becomes accentuated after death. The liver is of approximately normal size, reddish yellow, brownish yellow or "chamois leather" colour, and may show hæmorrhages. Microscopically a midzonal fatty degeneration is characteristic on the fourth or fifth day, but later all zones undergo necrosis, and the nuclei may contain acidophile inclusion bodies. The gall-bladder contains tenacious, dark bile. The kidneys are congested, and show cloudy swelling and fatty degeneration. Petechial hæmorrhages, casts and degeneration of the convoluted tubules are seen on section. The adrenals may show cortical fatty degeneration. The left ventricle is often dilated, and its muscle pale and flabby. Bradycardia is due to damage to the auriculo-ventricular bundle, and fatty degeneration of muscle cell-elements are common. Erosions and petechial hæmorrhage in the stomach and proximal duodenum occur, hence the coffee-ground vomit and the tarry blood in the entero-colon. The spleen is almost normal in size and appearance. The pleura and meninges may show hæmorrhages, the brain is congested, and the lungs congested and apt to show hæmorrhages.

Clinical pathology.—The outstanding pathological features are cloudy swelling and necrosis of the parenchymatous cells, especially of the liver and kidneys, and degeneration of the capillary endothelium, resulting in hæmorrhages. Jaundice and albuminuria with casts are thus produced. Hypoglycæmia related to liver inefficiency may occur from the fourth day onwards, while the van den Bergh may show a biphasic direct positive reaction and a positive indirect reaction of from 2 to 20 units. In the later stages the blood urea may be increased, and in monkeys Findlay found an increase in guanidine bodies. Though the leucocytes may vary from 3,000 to 15,000 per c.mm., leucopenia is the rule, the lowest counts occurring about the fifth to sixth day; the neutrophiles are decreased, the lymphocytes increased and the eosinophiles tend to disappear. The clotting time is markedly increased. The cerebro-spinal fluid is under increased pressure and may contain increased quantities of albumin and chlorides.

Symptoms.—The incubation period is from three to five days, but may be ten. Clinically, the disease is divided into: (1) Larval and mild forms; (2) Severe; (3) Malignant. In well-established severe cases the clinical features vary according as the liver, kidneys or heart bear the brunt of the attack, acute hepatitis and cholæmia, uræmia and anuria; and cardiac insufficiency being respectively manifest. Most cases show evidence of both renal and hepatic involvement.

1. *The larval and mild types.*—During epidemics, as well as where the

disease is endemic, aberrant and irregular types are not infrequent; transient fever of one to four days duration, perhaps associated with albuminuria, occurs with rapid return to health. Where the pyrexia persists over 48 hours, headache, vomiting, eye pain and mild jaundice may ensue. Diagnosis in the larval forms is dependent on showing that convalescent serum is protective.

2. *Severe or ordinary types.*—The typical case presents three stages: (a) the *sthenic*; (b) the stage of remission on the third or fourth day; (c) the *asthenic* stage. In the *sthenic stage* the onset, which often occurs at night, is sudden with chilly sensations or a rigor, the temperature rapidly rising to 102° F. or 104° F. There is severe pain in the back and limbs, frontal headache with flushed face, injected conjunctivæ (ferrety eye) and photophobia. Prostration is severe, often disproportionately so to the temperature (Carter). The tongue is pointed and red; anorexia, nausea and vomiting, which may be bilious, appear. Epigastric discomfort and tenderness are characteristic, and insomnia is frequent. Albuminuria generally occurs on the second day and steadily increases. The pulse is at first rapid (90 to 110 per minute) and of high tension with raised blood pressure, but later slows until by the third day it may be 60 to 70 per minute despite the fact that the temperature remains elevated. This is known as *Faget's sign*, the pulse actually falling away from the temperature. It also remains slow when the temperature rises again in the relapse. Constipation is the rule.

Stage of remission.—About the third or fourth day the temperature may fall to 100° F. or lower with amelioration of symptoms. Recovery may result or fever be re-established. Frequently this stage is absent altogether.

The asthenic stage.—The temperature rises again if it has remitted, turgidity of the face decreases, and jaundice now appears; it is first seen in the conjunctivæ and is not obvious in the skin until the fourth day of fever as a rule; sometimes, however, it is demonstrable on the third day. The gums are swollen and bleed on pressure, while the tongue is coated and later becomes dry and brown. The liver is tender and only slightly, if at all, enlarged, while the spleen is not palpable. Hiccough may be very distressing, and black or "coffee ground" vomit, tarry stools and skin petechiæ may occur. Bradycardia is marked (40 to 60 per minute) and the blood pressure low. The urine is acid and decreased in quantity; it contains urobilin and much albumin, granular casts and possibly bile salts, bile pigments, bile-stained epithelial cells, and red blood corpuscles. Anuria is frequent in fatal cases. After the intermission, the fever does not last as a rule more than three days.

Malignant forms.—In this type the temperature may reach 106° F. and profuse hæmorrhages, melæna, black vomit, epistaxis, hæmaturia, purpura, jaundice and anuria may develop by the third day. Symptoms referable to the nervous system such as hiccough, tremor, subsultus tendinum and delirium are also encountered, death from overwhelming toxæmia rapidly ensuing.

Complications.—Complications are uncommon, but boils, abscesses and troublesome jaundice, appearing for the first time in convalescence, may occur.

Diagnosis.—Difficulties in diagnosis are mainly encountered in atypical cases, especially early in an epidemic. In the average case fever associated with undue prostration and early and increasing albuminuria should at once arouse suspicion, while later, the tender liver, absence of splenic enlargement,

Faget's sign, hæmorrhages and jaundice appearing about the fourth day will be confirmatory. In blackwater fever, jaundice appears in the first 24 hours; in bilious remittent fever on or about the second day; while in Weil's disease it is generally found on the fourth or fifth day. Dengue, malignant tertian malaria, and relapsing fever also occasionally give rise to difficulty in diagnosis. Malaria, bilious remittent fever, and relapsing fever are generally associated with an enlarged spleen, while blood smears should reveal malaria parasites or spirochætes. Special laboratory investigations may be necessary to differentiate Weil's disease. In the larval forms of yellow fever intracerebral inoculation of susceptible mice with 0.03 c.c. of blood collected during the first three days of fever may reveal the virus. More frequently it will be necessary to take two specimens of blood at a fortnight's interval and establish a rise in the titre of protective antibody by the mouse protection test in order to establish the diagnosis.

Course.—If the patient survives, the acute disease rarely lasts longer than 10 days, and convalescence generally progresses slowly but surely once a normal temperature is established. Relapses are rare and generally fatal.

Prognosis.—The prognosis differs in various epidemics, the mortality rate varying from 10–70 per cent., the average being 20–30 per cent. Anuria, deep jaundice, black vomit, hæmorrhages and severe nervous disturbances are of grave significance.

Treatment.—**PROPHYLACTIC.**—The segregation of infected individuals in mosquito-protected wards, and the destruction of the adult and larval stages of mosquitoes (*Aedes*) have done much to stamp out the disease. Rubber gloves must be worn in collecting blood from all pyrexial cases in endemic areas. Convalescent serum affords temporary protection. All persons visiting or living in a yellow-fever area should be vaccinated with virus modified by tissue culture. A single subcutaneous injection of 0.5–1.0 c.c. produces protective antibodies and confers an immunity which probably lasts several years. No local reaction follows inoculation, but fever with headache and general aching may develop on the sixth or seventh day. Jaundice has frequently followed some three months after inoculation, but this is not due to the yellow-fever virus, but to the use of human serum containing the icterogenic factor.

CURATIVE.—Careful nursing of the patient in the recumbent position is essential, and as much fluid as can be taken is given during the acute illness, but food is contra-indicated. The juice of citrus fruits and dextrose and lactose are given in water; citrates should be added to the drinks to combat acidosis. Only when the temperature has been normal after the second paroxysm can a gradual increase in food be permitted—rice water, chicken soup, Benger's, custard, etc.—and even in convalescence it is only gradually increased. In severe cases, with vomiting, 2 pints of 5 per cent. dextrose, given intravenously every 24 hours, may be helpful; also tap water may be administered by proctolysis. Calcium lactate, grs. 60 daily, is advocated to neutralise the effects of guanidine intoxication. Unfortunately, though protective to monkeys, convalescent serum does not affect the course of the disease once symptoms have appeared. Symptomatic treatment includes the use of an ice bag locally for headache, a mustard plaster to the epigastrium for hiccough, hot fomentations and catheterisation for retention and sedatives for insomnia. Champagne may help the vomiting. On

admission a mild purgative is administered and constipation is subsequently treated by a daily enema. A cold sponge is indicated when the temperature exceeds 103° F.

PHLEBOTOMUS FEVER

Synonyms.—Papataci Fever; Three-day Fever; Sand-fly Fever; Pym's Fever; Dog's Disease.

Definition.—An acute specific fever lasting about three days due to a filterable virus and spread by *Phlebotomus papatasi*.

Ætiology.—The disease occurs in parts of Africa, Asia, Northern Argentina and is common in the Mediterranean basin, in India, Mesopotamia, Persia, etc., where it affects especially white races, though natives also suffer. Many thousands of troops were affected in the Middle East during 1940–1944. The virus is present in the peripheral blood for the first 24 to 48 hours, and female sand-flies sucking up such blood becomes infective six or seven days later, and remain so for life (Doerr). The virus may also be transmitted by the female *Phlebotomus* to the egg and larva (Moshkovsky). Blood taken on the first and second days may produce the disease on experimental inoculation, and volunteers bitten by infective sand-flies develop fever in two to seven days. One attack generally confers relative immunity, but second attacks are not uncommon.

The disease occurs in the summer and early autumn in the subtropics, as *Phlebotomus papatasi* passes the winter months in its larval stage. It breeds in cracks and crevices affording moisture, darkness and organic matter, and is found in stone and rubble walls, dug-outs, trenches, and surface soil. The adults shelter in similar situations. The females bite just after sunset and at dawn. Numerous bites occur over the wrists and ankles, where they produce itchy papules, which may vesiculate and give rise to localised swelling. The itching is severe, and may persist for 48 hours or longer or recur after an interval of several days in a sensitised individual who is rebitten.

Pathology.—This has been inadequately studied, as the disease is not fatal.

Symptoms.—The incubation period is two to seven days. Prodomata, such as malaise, vague pains, headache, and weariness, may usher in the disease. Generally the attacks commence suddenly with chilliness, shivering, lumbar pain and malaise. Rigors occasionally occur. The fever is short and sharp, reaching 101° F. to 104° F. by the evening of the first day. Severe frontal headache, increased by coughing, retro-ocular pain, accentuated by movement of the eyes or pressure on the globes, and toxic pains and stiffness in the muscles of the back, neck and legs are characteristic. The face is flushed and perhaps swollen, the conjunctivæ are injected (Dog's Disease), the skin is hot and dry, the tongue has a central fur, the throat is congested, and the fauces and palate are sometimes studded with small vesicles. Bradycardia is a feature of the disease. Drowsiness, sleeplessness, and irritability are common. The cerebro-spinal fluid may sometimes show increased pressure, some lymphocytes (10–30 per c.mm.), an increase in albumin, and a decrease in chloride. The blood picture shows a leucopænia with a relative lymphocytosis. Epigastric discomfort, nausea, vomiting and constipation may occur; occasionally diarrhœa is encountered.

After about 36 hours, the temperature begins to fall and reaches normal in three or four days. There may be concomitant sweating, vomiting, diarrhoea and epistaxis. Occasionally the fever only lasts for two days, and rarely it exceeds four days.

Diagnosis.—In the early stages it may be impossible to make a diagnosis with certainty. Influenza, dengue, paratyphoid, malaria, relapsing fever, typhus, infective hepatitis, and other fevers may need differentiation. In influenza the upper respiratory tract involvement, and in dengue the secondary rash and the more prolonged or saddle-back type of temperature, may assist diagnosis.

Prognosis.—Recrudescences are exceptional. The disease is never fatal. Convalescence is generally rapid, but extreme depression, malaise, asthenia, and digestive disturbances may persist for one or two weeks.

Treatment.—**PROPHYLACTIC.**—Destruction of sand-flies, by spraying of rooms, tents and dugouts, the avoidance of proximity to breeding-places, the use of repellants applied to the ankles, wrists and exposed parts at sunset and of sand-fly nets at night are measures designed to reduce the incidence of infection.

CURATIVE.—Cases are treated by rest in bed during the febrile period, cold sponging when the temperature exceeds 103° F., and a mixture of aspirin, phenacetin and caffein citrate. At onset, opium in the form of *Extractum opii liquidum* may afford considerable relief.

DENGUE

Synonyms.—Dandy Fever ; Break-Bone Fever.

Definition.—A specific fever, lasting five to seven days, caused by a filtrable virus which is transmitted by *Aedes aegypti* or certain other species of this genus. A saddle-back temperature chart, severe rheumatic-like pains in the limbs, backache, bradycardia, leucopænia and a measles-like eruption appearing about the third-fourth day are characteristic. Many atypical clinical forms occur.

Ætiology.—The disease occurs universally throughout the tropics and subtropics, where it is often endemic ; from time to time explosive epidemics or pandemics arise. All ages and both sexes are liable to infection. The virus is filterable, and exists in the blood for some 18 hours before onset and for the first three days of fever. It is communicable to man by direct blood inoculation during this period, or by the bites of certain species of *Aedes* mosquitoes. The mosquito takes 11 to 14 days to become infective, and remains so for life. The common vector is the domestic mosquito, *Aedes aegypti*, and owing to its habits the disease is especially common in towns on the sea coast. *Aedes albopictus* also transmits dengue in the Philippines, while *Aedes scutellaris* has recently been proved to transmit dengue to troops in New Guinea in areas in which *Aedes aegypti* is absent. The same virus transmitted experimentally to volunteers by the same batch of mosquitoes can give rise to a very variable clinical picture. Some volunteers fail to develop fever, though their blood contains the virus ; others may have a two-day fever ; others a saddle-back type of temperature chart ; and others continued fever of five to seven days' duration. Demonstrable immunity follows experimental infection.

Immunity also develops following natural infection, and when individuals suffer second or third attacks of dengue these tend to be of lessened intensity. The fact that large epidemics are separated by intervals of many years appears to depend on acquired immunity in the local population. Newcomers are always most prone to the disease.

Pathology.—Nothing definite is known of this, as the disease is only fatal in the presence of complications or intercurrent disease.

Symptoms.—In epidemics, the severity and clinical picture vary considerably at different times and in different areas, and though typical cases are always recognisable many atypical ones are encountered which do not conform to the classical picture.

The incubation period is generally five to ten days. In the typical case, three phases are recognised: (1) the stage of invasion, (2) the stage of remission, and (3) the stage of secondary rash and terminal fever. Prodromata include general malaise and pains in the limbs. Generally the onset is absolutely sudden, with a rapidly rising temperature of 102° F. to 105° F., associated with headache and aching eyeballs, more marked on movement. The skin, especially of the face, is congested and shows a general flushing—the so-called primary rash. Backache is very severe, and much pain occurs at the muscular insertion about the joints. Insomnia, initial depression, anorexia, vomiting, and constipation are not infrequent. The pulse, at first rapid, soon begins to slow, and after three to four days the temperature falls by crisis; this may be accompanied by diarrhoea, sweating and epistaxis. Symptoms now improve, but after 12 hours to three days the temperature rises again, producing the saddle-back chart. Pains and depression recur, and a roseolar rash, fading on pressure, appears; it is best seen on the dorsal surface of the hands and feet but also involves the face, neck and trunk. The rash simulates measles but lacks its dusky red appearance. Occasionally it is punctiform, and then somewhat resembles the eruption of scarlet fever. A rose-red flush of the palms of the hands and soles of the feet is not infrequent. Occasionally dengue rashes become petechial. The desquamation is furfuraceous in type, may be associated with marked itching and may persist for two weeks. A leucopenia with lymphocytosis is characteristic. Glandular enlargements may occur, and in some epidemics adenitis is present in at least 50 per cent. of cases. Two or three days after the secondary fever and rash appear, the temperature falls and convalescence begins.

Other clinical types are frequently encountered. One type presents a one-phase fever like sand-fly lasting two to three days; another is characterised by continued fever of five to seven days' duration, with a terminal crisis; the rash is by no means invariable.

Complications and Sequelæ.—General debility, asthenia, anorexia, insomnia and mental depression may persist well into convalescence, and persistent rheumatic-like muscular pains in the vicinity of the joints may prove very troublesome.

Diagnosis.—Influenza, sand-fly fever, yellow fever, rheumatic fever, measles, German measles, scarlet fever, secondary syphilis, leptospirosis, malaria, para-typhoid, and typhus may be confused with dengue. The respiratory involvement in influenza; the early albuminuria and jaundice in yellow fever; the swollen joints in rheumatic fever; Koplik's spots and early coryza of measles; the rapid pulse, adenitis and leucocytosis in scarlet

fever—these will often enable a diagnosis to be made. Specific laboratory tests, the clinical features and the course of the disease will assist in differentiating the other maladies mentioned.

Prognosis.—Different epidemics vary in virulence, but the death-rate is extremely small.

Treatment.—**PROPHYLACTIC.**—Prevention of breeding and destruction of the larvæ and adult mosquito vectors will prevent the disease. As *Aedes* is a day-biting mosquito, it is important to treat all dengue patients under mosquito nets for the first three days of their fever, and for hospital staffs to use anti-mosquito repellant lotions and take other appropriate precautions in daylight hours as well as at night.

CURATIVE.—No specific treatment is available. The patient should be kept in bed on a light diet for at least three days after the fever has terminated. An aspirin, phenacetin and caffein citrate mixture is helpful for toxic pains; and sedatives and cold sponging may be necessary to induce sleep.

During convalescence, tonics, good food, and a change of climate may be necessary to restore health in asthenic and depressed dengue patients.

LYMPHOGRANULOMA INGUINALE

Synonyms.—Climatic Bubo; Tropical Bubo; Lymphopathia Venereum; Poradenitis.

Definition.—A venereal disease due to a filterable virus characterised by a herpetiform chancre on the genitalia or peri-anal region, inflammation of the corresponding regional lymphatic glands, and fever. In males the inguino-cruro-iliac glands and in females the pararectal and pelvic glands are chiefly involved. Chronic ulceration and elephantiasis of the pudenda are not uncommon in females, and inflammatory stricture of the rectum may occur in both sexes.

Ætiology.—The disease has a world-wide distribution, but is especially common in China, Japan, Malaya, East and West Africa, and in North and South America. Though more common amongst coloured races, especially negroes, it is being recognised with increasing frequency in Europe. The disease occurs mainly in adults, is essentially venereal in origin, and is commonly acquired in the tropics and sub-tropics following coitus with native women. Sailors often acquire the disease in Eastern ports. The virus particle has a diameter of 0.125 to 0.175 μ , is filtrable, and was first successfully transmitted to monkeys by intracerebral inoculation of bubo pus by Hellerström and Wassén. Mice are similarly susceptible. In guinea-pigs large buboes may follow the subcutaneous injection of sterile bubo pus. Surgeons have developed axillary buboes from lesions on the fingers when operating on infected patients, and children have acquired infection from simple contact.

Pathology.—The extirpated glands show marked periadenitis, and form conglomerated masses. The cut section often presents a reddish or violet tinge. Foci of purulent softening may occur, and sometimes pus cavities, containing thick muco-pus of a grey to light green colour, are produced by their coalescence. Microscopical sections of the bubo reveals granulomatous tissue, epithelioid cells, fibroblasts, occasional giant cells, and polymorphonuclear leucocytes; epithelioid cells with palisade arrangement are very

characteristic. Chromatin staining inclusion bodies, known as Gamma bodies, are found within lymphocytes and plasmocytes in the infected glands.

Symptoms.—In males, the primary lesion is as a rule overlooked. It occurs as a small herpetiform ulcer, generally situated in the coronal sulcus on the penis, and appears a few days to three weeks after coitus. Swelling of the median group of inguinal glands draining the ano-genital region follows in about two or three weeks, the limits being one to six weeks. Bilateral glandular involvement occurs in 35 per cent. of the cases. The onset is generally insidious, with slight stiffness or tenderness in the groin, and fever. Often pain is absent; rarely it may be severe. The skin is at first red, but as swelling of the glands with periadenitis and hard brawny infiltration proceeds, it changes to a bluish-violet tint. The conglomerated glands are hard to the touch, generally only slightly tender, and show no fluctuation unless suppuration is advanced. Fistulæ form in about half the cases. Though the iliac glands are frequently enlarged and palpable, they never present clinical evidence of suppuration. Healing with scarring may occur within two months or be delayed 1½ years. The general symptoms include fever, anorexia, weakness and loss of weight. Although the fever is usually remittent in type no characteristic temperature chart is present, and not infrequently the temperature becomes normal in seven to ten days, but sometimes it is prolonged and a typhoid-like state supervenes. Recurrent fever is occasionally associated with extension of the adenitis. Rheumatic and allergic skin manifestations are not uncommon, and include painful red swollen joints, erythema nodosum, erythema multiforme, scarlatiniform and urticarial eruptions.

In females, primary lesions may occur on the genitalia or peri-anal region, and the para-rectal glands are commonly involved; these glands often suppurate and form fistulæ which may open into the vagina, the rectum, or the skin near the anus. The disease runs a chronic course; fibrous stricture of the urethra, vagina and rectum may develop, or elephantiasis of the vulva (esthiomène) follow lymphatic obstruction. Polypoid swellings may occur about the anus, while the lower portion of the rectum may ulcerate and become converted into a narrow indurated ulcerated tube, with widespread fistulæ below the stricture. According to Stannus this is generally situated some 3 to 8 cm. above the anus. Rectal stricture is more common in females—especially in prostitutes—and is associated with the passage of blood, mucus and pus from the bowel, and increasing constipation.

Diagnosis.—Climatic bubo has been called the sixth venereal disease, and the history and clinical features are most important in making a correct diagnosis. Where periadenitis and induration are extreme, actinomycosis may be simulated. Herpes genitalis, filarial adenitis, septic and tuberculous adenitis, venereal bubo the result of chancroid, gonorrhœa and syphilis, as well as other buboes, such as result from plague, rat-bite fever and tularemia, may need differentiation. Histological section of material obtained at biopsy and Frei's intradermal test, using a 1 in 10 dilution of virus-containing pus sterilised at 60° C., may be of assistance; 0.1 c.c. of this antigen is injected intradermally, readings being made at the end of 48 hours. A positive reaction is characterised by the appearance of a reddish, infiltrated papule, measuring from 7.5 to 20 mm. in diameter. It is regarded as a manifestation of cutaneous allergy, and is said to be specific for climatic bubo. Animal inoculation and the mouse protection test may be resorted to in doubtful cases.

Lesions in the ano-genital region must be differentiated from filarial elephantiasis and ulcerative granuloma pudenda. Polypoid swellings should be distinguished from piles, simple polyposis and bilharzia polyps. Rectal stricture which is not due to surgical or other trauma or new growth is almost certainly caused by this virus; in the past it has generally been erroneously attributed to gonorrhoea, chancroid, syphilis, or tuberculosis.

Prognosis.—The disease runs a different course in different individuals. In males, unless the rectum be involved, the outlook is good though the disease may last many months. In females, with extensive ano-genital manifestations, such as fibrous strictures and multiple fistulae, permanent invalidism may result.

Treatment.—The patient should be put to bed, have a nutritious high vitamin diet, and given a course of sulphapyridine or some similar sulphonamide, as some patients appear to be cured by this treatment. If the glands are small and have not suppurated they are best left alone. If suppuration has taken place, aseptic aspiration may be undertaken. Excision at this stage may result in secondary infection, and should not be attempted. When operative intervention is practised in early cases, it should be remembered that too extensive removal of the groin glands may result in elephantiasis and the femoral chain must be left intact.

C. THE MYCOSES

Numerous fungi are pathogenic to man, and the lesions caused thereby are conveniently described as the mycoses.

Some of the diseases, for example the ringworms, are described in other sections. Six of them will be described here—actinomycosis, mycetoma, sporotrichosis, aspergillosis and blastomycosis, the lesions of which are of the nature of infective granulomata,

ACTINOMYCOSIS

Synonym.—Ray-fungus Disease.

Definition.—A local infection, tending to become general, due to the *Streptothrix actinomyces*, producing granulomatous lesions chiefly in the jaw, skin, lung and digestive tract.

Ætiology.—*Actinomyces bovis* was first described by Böllinger in 1877 as the micro-organism producing large, hard, sarcomatous-like masses occurring about the jawbones of cattle, and in the following year Wolff and Israël found the same organism in human cases.

The characteristic of the disease is a suppurative lesion, the pus from which contains visible granules which, examined microscopically, are seen to have a centre of a closely meshed filamentous network, with a border of radially arranged striations, often ending in club-shaped bodies. Formerly these club-shaped bodies were thought to be spores, but they are now regarded as hyaline thickenings of the sheaths of the threads. The clubs are only found in preparations made from pus from active lesions, or in cultures on media in which serum or blood is employed.

It is essential in examining suspected pus to isolate a granule. If granules be not readily detected in the wound or in the pus, Colebrook has pointed out that if pus be vigorously shaken in a tube of water the granules, not being emulsified, will sink to the bottom and may be removed by a pipette. Microscopical examination is very much facilitated by crushing the granules between two slides. The mycelial filaments retain Gram's stain, while the clubs lose it and take the counter-stain. Culture is in any case difficult, depending to a large extent on the amount of secondary infection. To eliminate this as far as possible the granules should be well shaken in a sterile saline solution, and then after crushing between sterile slides should be sown on to glucose agar plates which are incubated anaerobically, or crushed granules may be shaken up into melted glucose agar which is aspirated into long sterile tubes according to the method of Vignal. Numerous subcultures may be necessary to complete the isolation of the organism.

Mode of invasion.—Till recently the view has been held that actinomycosis was conveyed to cattle and man from vegetable sources. Colebrook, in a review of 28 cases coming under his observation, brings forward strong reasons for believing that the fungus may be present under normal conditions in the alimentary tract. He quotes Lord as finding similar organisms in carious teeth and tonsillar crypts, and himself found not dissimilar filamentous organisms in each of six carious teeth examined. He also has shown that the serum of heavily infected patients causes agglutination of suspensions of actinomyces, as also does the serum of inoculated rabbits. The same observer supports the observation of Klinger as to the frequent association with actinomyces bovis in actinomycotic lesions of a minute Gram-negative cocco-bacillus, to which Klinger gave the name of *Bacillus actinomyces comitans*. The significance of the association is not known.

Symptoms.—These depend upon the anatomical distribution of the granulomata.

1. **THE JAW AND ADJACENT STRUCTURES.**—When the infection occurs in these parts the patient presents a swelling very like a sarcoma, generally

about the angle or ramus of the mandible. The swelling may, however, affect the submandibular tissues and lymph glands rather more than the jaw itself, and one of the writers has recently seen a case in which the lesion was confined to the glands. The swelling is tender, somewhat painful, and not generally so hard as in sarcoma. It may show one or more spots of softer consistency than the rest of the lump. In most cases there is no obvious source of infection inside the mouth; the assumption is—in the light of observations quoted above—that the avenue of invasion is a carious tooth, or the gums and periodontal membrane.

2. THE INTESTINES; APPENDICITIS.—The favourite site of infection is the cæcum and appendix region. The disease manifests itself either as an attack of appendicitis, most often acute, in which case the diagnosis is made only at the time of laparotomy; or as a slowly growing lump in the right iliac fossa, with some pain, tenderness, and constitutional disturbance, in which case suspicion may be aroused as to its nature, if it be remembered that this region is a site of election for the ray fungus. There is a tendency for the infection to spread from the ileo-cæcal region—(a) to the adjacent *peritoneum*; (b) to the *abdominal wall*; (c) to the *liver*. For this reason it is rare to find the lesion confined to the appendix by the time operation takes place. For this reason, too, the first evidence of cæcal infection may be the involvement of the parietes in the lower right quadrant of the abdomen, in which case there is always a probability that the infection has spread from the bowel. The *liver* is sometimes involved alone, that is, without obvious intestinal infection. The disease is only to be distinguished from abscess by puncture or by free incision.

3. THE PLEURA AND LUNG.—Actinomycosis in these tissues is by no means rare (see section on Respiratory System, pp. 1236, 1290), and the disease should constantly be borne in mind by the practitioner when faced with an obscure case in which indefinite physical signs appear at one base, with cough, fever and (not seldom) hæmoptysis. In some cases a fairly frank pleuritic effusion appears, and the bacteriological examination of the exudate reveals the nature of the disease. In other cases the clinical picture resembles a basal tuberculosis. As the disease progresses the differential diagnosis lies between ray fungus, bronchiectasis and new growth. Hæmoptysis which recurs in the absence of any evidence of tuberculosis in an obscure case of pulmonary disease, is highly suggestive of actinomycosis of the lung. The later stages of the disease still resemble pulmonary tuberculosis; wasting, intermittent fever, purulent expectoration, cough and physical signs of progressive lung infiltration with destruction.

4. THE SKIN.—Granulomata sometimes appear in the skin and subcutaneous tissues (a) alone, or (b) complicating the disease in deeper structures.

(a) The neck and scalp are the parts most often affected. The initial lesion is a rounded swelling, not very acute, and therefore resembling a tuberculoma rather than the result of a pyogenic infection, but usually firmer in texture and larger than the lesion seen in tuberculosis of the skin. It has therefore to be distinguished from sarcoma and from gumma. As the lesion progresses it involves the subcutaneous tissue and tends to ulcerate, after the appearance of one or more soft and dusky-red areas on it. When ulceration occurs at these points, pus escapes, and this contains the tell-tale granules characteristic of the infection. At this stage the appearance is not unlike

that of a chronic carbuncle or a suppurating gumma. Ultimately the skin "breaks down" over a considerable area of the swelling, and a chronic ulcer forms, which discharges freely.

(b) Similar skin lesions appear not seldom in association with primary infections of deeper structures, these superficial deposits having the significance of metastatic pyæmic deposits.

5. THE BRAIN.—The brain, like the skin, may be infected by direct spread from an adjacent lesion, or it may suffer by way of a general pyæmic process. In a case under the observation of C. Ernest West and Horder a chronic otitis media was complicated by granulomata in the scalp, from which the streptothrix was demonstrated in films and grown in tubes of blood-broth. Cerebral symptoms developed, and the patient died comatose. At the post-mortem examination a large abscess was found in the centrum ovale of one hemisphere, and the mycelial threads were found in the pus in considerable numbers.

Diagnosis.—Hints have been given in the preceding account relative to the differential diagnosis from tuberculoma, sarcoma, pyogenic infection and gumma. *The chief reason why actinomycosis goes unrecognised is that the possibility of its existence is overlooked.* All materials from a suspected case (pus, pleural exudate, sputa, material from liver puncture, excised lymph glands, etc.) should be carefully examined for mycelium, and the bacteriologist should have his attention drawn to the possibility of its presence. Sputa from a case of recurring hæmoptysis, in which a negative report in respect of tubercle bacilli has been returned on several occasions, have been found to contain threads of actinomycetes when the necessary investigation has been specially asked for.

Course and Prognosis.—Although these vary much, there is, as may be inferred from remarks already made, a tendency for ray-fungus infection to become pyæmic in character. It is this feature which gives the serious note to prognosis in all cases. In lesions about the jaw and in skin infections, that are primary and not associated with visceral infection, the outlook is not nearly so bad as when the lungs, liver or intestinal tract are involved and when the skin lesions are multiple and secondary. Early diagnosis, if possible before secondary infection (usually staphylococcus) has taken place, adds greatly to the chance of recovery. One of the most important points in connection with prognosis is the uncertainty as to the complete extirpation of the fungus after treatment has been apparently successful. Relapses are common, and must be allowed for in any thorough programme of treatment.

Treatment.—So soon as the diagnosis is made, the question should be raised whether or not radical surgical measures are practicable. If they are they should be pursued without delay; any abscess or infected area should be drained, or incised and freely curetted; infected lymph glands should be excised; doubtful teeth should be sacrificed. Conflicting are the reports on the value of sulphonamide therapy in this infection; one full course of sulphathiazole or sulphapyridine (see pp. 17, 18) is certainly worthy of trial. If it fails, the exhibition of potassium iodide in full doses should follow these surgical measures, or should take their place in all cases in which they are for some reason impracticable. In some cases it is reasonable to try the patient's response to iodide before planning operative measures. The drug

should be given freely diluted with water, and it should be gradually increased from an initial dose of 30 grains in the day to 60 grains, or even to 120 grains if this amount can be tolerated. If recovery takes place the iodide treatment should be renewed for certain periods now and again to guard against relapses.

Vaccine therapy is of help when combined with adequate surgical measures. The preparation of an autogenous vaccine presents few practical difficulties, and stock vaccines are available, containing 25-million mycelial fragments per cubic centimetre. If staphylococci be also present the appropriate vaccine may be combined with the mycelial one.

Treatment by X-rays has also been advocated as a supplementary measure.

SPOROTRICHOSIS

In this disease, which is much less common than actinomycosis, lesions (granulomata) appear in the skin, and rarely in the muscles and bones.

Ætiology.—The causative microbe was first described by Schenk in 1898. Two varieties, *Sporotrichum schenki* and *S. beurmanni*, were originally described, but are now generally regarded as identical. The organisms occur in pus as oval or fusiform spores, and grow in culture as a colourless branching septate mycelium, with clusters of brown fusiform spores on the ends of the filaments. Occasionally the spores are arranged round the filaments. They stain well with the aniline dyes, but irregularly with Gram's stain. Growth occurs under aerobic conditions only, and on ordinary laboratory media. Cultures are best made from closed lesions, which should be punctured with a wide-bore needle, and the material aspirated should be thickly sown on glucose agar plates, which should be kept at laboratory temperature. The colonies, which appear in from 4 to 10 days, are very characteristic. At first white, thick and leathery, they later become convoluted and coffee-coloured, and still later may become black. Laboratory animals, especially mice and rats, are susceptible, the lesions resembling those in man; but the disease is seldom fatal. The serum of infected individuals agglutinates the spores of the organism, and specific immune bodies can be demonstrated by complement-fixation tests.

Symptoms and Diagnosis.—See p. 1482.

Treatment is on the same lines described for Actinomycosis.

ASPERGILLOSIS

Infections with aspergillus, usually *A. fumigatus*, have been observed in the middle ear, on abraded corneæ and in the lung. The organism is of the group of Ascomycetes; it grows on ordinary laboratory media, and frequently occurs as a contamination.

Cases of lung infection are not very rare (see p. 1236). They resemble cases of chronic pulmonary tuberculosis very closely; indeed, they are generally mistaken for this disease until investigation of the sputa reveals their true character.

HORDER.

A. E. GOW.

JOHN MATTHEWS.

MYCETOMA

Synonyms.—Madura Foot ; Fungus Foot ; Pseudo-actinomycosis.

Definition.—A chronic granulomatous condition affecting especially the feet, characterised by marked swelling and the appearance of external nodules connected with deeper sinuses which exude oily, purulent fluid containing various coloured fungoid granules.

Ætiology.—The disease is endemic in certain parts of India, especially in the Madras Presidency (Madura), but it also occurs in Ceylon, Madagascar, parts of Northern Africa such as Egypt, the Sudan and Algiers, as well as in Cochin-China, Senegambia, the United States, West Indies, and South America. It is found in country districts, and generally attacks those who go barefooted, the mycetoma fungus probably gaining access through thorn punctures, small cuts or abrasions. Males are more commonly affected than females, and the disease is especially prevalent in the third and fourth decades of life, being generally confined to natives. Many different fungi which have the capacity in animal tissues to produce grains composed of hyphæ have been described as causing mycetoma. Laveran divides them into two groups : (1) the Actinomycoses, caused by fungi of the genus *Actinomyces* (*Discomyces*, *Nocardia*, etc.) ; (2) the Maduramycoses, caused by true fungi, the most important of which is the genus *Madurella*. White, red and black varieties of mycetoma occur clinically.

Pathology.—On section through the softened, jelly-like tissue, sinuses and cystic dilatations communicate with external nodules and internal granulomatous infiltrations which ultimately implicate muscle, fascia and bones, forming a honeycombed cheesy mass. Both the cysts and sinuses are filled with whitish-yellow, red or black granules like fish's roe, which microscopically show narrow, nucleated threads and peripheral, club-like swellings. Section shows fungoid granules surrounded by mononuclear and leucocytic infiltrations and by fibrous-tissue cells.

Symptoms.—The incubation period is not definitely known, but in about 50 per cent. of cases there is a history of trauma ; many weeks or months may elapse before local lesions develop. The first signs are the presence of one or more hard, painless, subcutaneous nodules which are about 0.5 to 1.0 cm. in diameter and generally involve the sole of the foot, and more rarely the hands, face and limbs. Unlike actinomycosis the glands and viscera are never affected, adenitis, if present, being due to secondary bacterial infection. After several months swelling increases, the nodules break down and ulcerate, sinuses are formed and discharge their characteristic contents. Finally, the parts become riddled with sinuses, exuding foul-smelling, semi-purulent fluid. The foot becomes more and more swollen and distorted, but it shows little tendency to pain or hæmorrhage. In the early stages the general health is not adversely affected, but later anemia and cachexia develop if secondary bacterial infection supervenes.

Diagnosis.—This is readily made by finding the characteristic fungi in the pus, but the identification of the actual species of mycetoma requires detailed laboratory investigation.

Prognosis.—There is no tendency to natural cure, and if untreated the

prognosis is bad, the patient generally dying from intercurrent disease or secondary infection within fifteen years of onset.

Treatment.—**PROPHYLACTIC.**—Protection of exposed parts, like the feet, from thorns and spikes of barley would probably prevent the disease. Walking barefooted is to be avoided.

CURATIVE.—Surgery is the only satisfactory treatment. In the early stages curettage, or local excision of the nodules with the electric cautery may prove successful. In sinus-riddled feet amputation is the only cure.

BLASTOMYCOSIS

Synonyms.—Gilchrist's Disease ; Chicago Disease.

Definition.—A term applied to certain chronic granulomatous lesions of the skin or viscera, caused by yeast-like blastomyces.

Ætiology.—People of any age are susceptible, but males in the industrial classes are most often affected. The disease was especially prevalent in Chicago, but is now known to occur in all parts of the world. Castellani holds that there are at least three different species of Blastomycoides—*B. immitis*, *B. dermatitidis* and *B. tularensis*.

Pathology.—Nodules, gummata, papillomata and ulcerations may be produced in the skin, and tumour-like granulomata and abscesses in the viscera. The pathological lesions resemble the tissue reactions induced by the tubercle bacillus, but the central necrosis is less, and yeast-like organisms are present.

Symptoms.—The clinical manifestations are very variable. Jacobson divides the primary cutaneous manifestations into papulo-ulcerative, papillomatous and gummatous types: cutaneous lesions secondary to systemic blastomycosis consist of superficial ulcers with granulating bases which exude pus or form crusts. Local pain and discomfort are produced.

In systemic blastomycosis the clinical picture resembles a subacute or chronic pyæmia, and almost any organ may be involved; the lung (95 per cent.) and kidneys (30 per cent.) are most frequently implicated, producing localising features resembling pleurisy or pneumonia on the one hand and nephritis on the other. Osseous involvement and blastomycotic meningitis may also occur.

Diagnosis.—This depends on the demonstration of blastomyces in pus, sputum or cerebro-spinal fluid; moist specimens are prepared by mixing with a drop of sodium hydroxide (10 to 30 per cent.) and examined microscopically, when the round or oval, highly refractile bodies (5 to 20 μ) surrounded by a hyaline capsule, may be observed. They may also be cultured on glucose agar.

Prognosis.—Cases with localised cutaneous lesions as a rule ultimately recover if properly treated, but in systemic blastomycosis 90 per cent. of cases end fatally in a few weeks to three years (Jacobson). Cerebro-spinal cases invariably die.

Treatment.—Skin lesions should be radically treated by complete resection with the cautery, or curetted and cauterised. Radium and X-ray treatment combined with full doses of iodide, i.e. 20 to 60 grains three times a day, are sometimes successful. Systemic blastomycosis cases should receive large amounts of iodide. Autogenous vaccines are worth a trial.

COCCIDIOIDOSIS

Synonyms.—California Disease; Coccidioidal Granuloma.

Definition.—An acute, sub-acute or chronic disease, characterised by granuloma formation in the skin or viscera, caused by the hyphomycetous fungus, *Coccidioides immitis*.

Ætiology.—The disease is endemic in certain parts of North America and affects persons of any age. Males of the working class are particularly prone. The causative agent is *C. immitis* which appears in the tissues or pus as a spherical, double-contoured body measuring 5 to 60 μ . The fungus is readily cultured and laboratory animals are susceptible.

Pathology.—The lesions are those of an infectious granuloma and the tissue changes include tubercles, caseation, necrosis, abscess formation, cavitation, fibrosis and even calcification.

Symptoms.—As in blastomycosis both cutaneous and systemic manifestations may be present, but the latter are more frequently observed. Acute, sub-acute and chronic types are described. Nodular lesions may involve the dermis, and flaccid tumours, gummatous-like ulcers, and abscesses containing thick mucoid pus may be found in the subcutaneous tissues. A scrofulodermic type of lesion involving the superficial lymph glands, especially of the neck, is also described. Systemic coccidioidosis frequently involves the lungs, when it resembles tuberculosis, though early hæmoptysis is rare. Meningitis and involvement of the bones of the foot, ribs and vertebral column may occur.

The disease is progressive in character, lasting a few weeks to several years.

Diagnosis.—Numerous diseases including tuberculosis, syphilis, blastomycosis, sporotrichosis, mycetoma and bacterial osteomyelitis may be simulated. Diagnosis essentially depends on isolating *C. immitis* from pathological exudates. X-rays may be of assistance where bone is implicated.

Prognosis.—The more chronic type of the disease responds if treated early, but once the viscera are involved recovery is doubtful. Acute cases die.

Treatment.—X-rays and iodides have proved disappointing. Jacobson recommends intramuscular injections of colloidal copper every four to seven days, and coccidioidin (exotoxin and endotoxin) every 8 to 14 days, the interval being determined by the local and constitutional reaction. Carbon dioxide snow may be used for isolated local lesions. Where the lesions have been confined to one limb early amputation has resulted in cure.

TORULOSIS

Definition.—An infection produced by a yeast-like organism, *Torula histolytica*, possessing a special affinity for the cerebro-spinal system and lungs.

Ætiology.—The disease affects both men and women and has a widespread geographical distribution. Species of the genus *Torula* reproduce only by budding without mycelial or endospore formation and do not ferment sugar; in pus and cerebro-spinal fluid they appear as ovoid or spherical structures, measuring 3 to 15 μ , with definite cell walls (Jacobson).

Pathology.—Chronic leptomeningitis is present, while the brain shows tubercles and gelatinous cyst-like structures in which torulæ abound. Clear spaces containing gelatinous material are found round the parasites in the tissues, and this constant finding led Stoddard and Cutler to name the parasites *Torula histolytica*. Similar lesions may occur in the lung which may be honeycombed, the interstices being filled with gelatinous material.

Symptoms.—Occasionally localised torulosis involves the skin or mucous membranes, but much more commonly there is primary involvement of the cerebro-spinal system. The lungs are generally secondarily implicated, but we have observed one case in which the patient was treated for pulmonary tuberculosis many months before meningitis ensued; at autopsy the lungs showed extensive gelatinous infiltration.

Diagnosis.—Clinically, these cases simulate tuberculous meningitis, and unless cultures are made the torulæ may readily be mistaken for lymphocytes. The cerebro-spinal fluid is under increased pressure, and contains excess of globulin and lymphocytes, but the sugar reaction is negative.

Prognosis.—The course of the disease is sub-acute or chronic, lasting a few weeks to two years, with an average duration of $4\frac{1}{2}$ months. In localised infections the outlook is fairly good, but systemic torulosis is practically always fatal.

Treatment.—Surgical resection with the cautery is the treatment for local lesions. In generalised infections sulphonamide therapy is worthy of trial.

RHINOSPORIDIOSIS

Definition.—A chronic disease due to *Rhinosporidium seeberi* (Wernicke, 1903), which produces nasal polypi and papillomata of the cheek, conjunctiva and lachrymal sac.

Ætiology.—Until recently the organism was regarded as a protozoon, but Ashworth has now shown it to be a vegetable mould belonging to the order Phytomycetes. The younger forms are rounded bodies, some 6 microns in diameter, possessing a capsule, a single nucleus and cytoplasm containing food granules. Multiplication by fission occurs and sporangia or large cysts, 250–300 microns in diameter, with a cellulose coating result; later, numerous daughter cysts are discharged from a definite pore in the wall of the mother cyst. Infections have been recorded from India, Cochin-China, Ceylon, Argentine and North America. The mode of transmission is unknown, but a similar if not identical fungus, *Rhinosporidium equi*, affects the horse, and man may acquire the disease from this source.

Pathology.—The organisms develop in connective tissue cells, causing fibroblastic activity, round-cell infiltration and epithelial proliferation. Polypi result which may involve the nose, conjunctiva, lachrymal sac and ear, and papillomata of the penis and vulva have also been described.

Symptoms.—A history of nasal symptoms extending over years may be obtained. The polyps are soft, vascular, bleed easily and show a marked tendency to recur.

Treatment.—The polyps are removed surgically, a wire snare often being employed. Wright has observed tumours disappear after a course of tartar emetic intravenously.

N. HAMILTON FAIRLEY.

D. SPIROCHÆTAL INFECTIONS

SYPHILIS

Definition.—A specific disease due to entry of a micro-organism (*Spirochæta pallida* or *Treponema pallidum*) into the tissues, either by inoculation into the skin, mucous membrane, or veins (acquired syphilis), or by transmission *in utero* (congenital syphilis).

In acquired syphilis, unless conveyed by transfusion, a primary sore commonly develops at each site of inoculation, and may be followed after a few weeks by a succession of lesions of the skin, mucous membranes, subcutaneous tissues, arteries, muscles, bones, viscera and central nervous system, which may recur again and again at varying intervals throughout the patient's life. After many years, degeneration of the parenchyma of the brain (general paresis) or of the spinal cord (tabes dorsalis) may develop. From an early stage changes in the blood serum can be detected by the Wassermann and various flocculation tests. Any or all manifestations, even the primary, may be omitted. In congenital syphilis and in syphilis acquired by transfusion the systemic disease is the first manifestation.

Ætiology.—The specific micro-organism was discovered by Schaudinn in 1905 and named by him *Spirochæta pallida*. Subsequently this was changed to *Treponema pallidum*, but the original name is preferred by many workers. *S. pallida* is a minute organism which in fresh specimens under dark-ground illumination appears as a bluish white, very delicate corkscrew. Its length varies from 5 to 24 μ (average 8 to 10 μ); the distance between individual coils is 1 μ , and the depth of each coil is 1 μ . It is very active in its own ground but slow in moving from place to place. It alternately contracts and expands its coils, bends into loops or forms itself into a right angle. It has been demonstrated in every syphilitic lesion, including the brains of general paralytics. It has a life of only a few hours under natural conditions outside the body, and is killed at once by drying, by comparatively low degrees of heat, and by much feebler antiseptics than suffice to destroy ordinary pathogenic organisms.

The usual methods of transmission are by sexual intercourse and to the fœtus *in utero*. It does not seem necessary for a person transmitting the disease by intercourse to be suffering at the time from syphilitic lesions of the external genitals, and it is clear that often the semen contains the micro-organism. The period during which a person suffering from syphilis is liable to convey the disease by sexual intercourse varies; after the second year the chances diminish, and it is unusual for infection to be passed on in this manner after the fifth year. There is no doubt, however, that in the case of the fœtus, although the mother is most dangerous in the first five years of her infection, this may be transmitted up to a much later period, and there is, in fact, no limit to the length of time during which an infected mother may transmit the disease to her unborn child; infection occurs most often in the second half of pregnancy. Accidental infection usually results from contamination of any minute abrasion with secretion from a syphilitic lesion. The most dangerous from this point of view are the primary sore and the

early secondaries of acquired syphilis and the early lesions in congenital syphilis, but although it is possible to infect an animal with secretion from later or tertiary syphilides, the chances of conveying the disease at this period by ordinary social intercourse are extremely slight. Even in the earlier stages, owing to the low resistance of the organism to external agencies, the risks of accidental infection by ordinary social intercourse appear to be very slight, judging by the great prevalence of syphilis and yet the very low proportion of extragenital chancres in countries where the standards of personal hygiene are equal to those in Western Europe. A number of instances of infection by transfusion of blood have been recorded, and they include cases in which the donor was still in the incubation stage; on the other hand, tertiary syphilites have now been used as donors in cases of emergency in a number of instances without harm to the recipients, and it is clear that the older the infection the less likely is the micro-organism to be in the blood stream.

Pathology.—Kolle and Evers have shown that, after inoculation by scarification, the micro-organism has reached the nearest lymph glands of a rabbit in half an hour. The syphilitic lesion of every stage is histologically the same—a granuloma composed of a collection of epithelioid cells, plasma cells, very numerous lymphocytes and some giant cells, with obliterative endarteritis of the vessels. The pathology of syphilis as it affects the nervous and the cardio-vascular systems is discussed in the sections dealing with those parts of the body. Here it may suffice to sketch the main general effects of syphilis on the vessels, since they explain a large proportion of the evil results of a syphilitic infection. The changes in the vessel wall may lead to aneurysmal dilatation, as in the case of the aorta and other large arteries of the body, and in the cerebral vessels. The aortic valve may be involved in syphilitic meso-arteritis, with resulting regurgitation. A common result of syphilitic arteritis of smaller vessels is thrombosis of the vessel, with important effects resulting from failure of the blood to reach the part supplied. In tertiary lesions the cutting off of nutritional supplies to the centre and the action of the toxin lead to necrosis and liquefaction, as seen in the clear-cut ulceration which often characterises tertiary syphilitic granulomata. If bone is involved in the tertiary gumma it may necrose throughout, as in the flat bones, or only partially, as in the long bones. Where necrosis does not occur, the granulomatous tissue of a syphilitic lesion tends to become fibrous, though at the same time natural forces work towards its removal. If the exudate is comparatively small, as in some primary and in practically all secondary lesions, the exuded cells may all be removed. If the exudate is a large one, a considerable proportion of it may reach the fibrous stage before the natural scavengers have had time to remove it. Thus many primary lesions are marked by hard scars for years afterwards, and gummata, their centres having liquefied, may be enclosed by dense connective tissue. Bone gummata are often ringed by heaped-up bone of ivory hardness.

Scarring from formation of fibrous tissue and its subsequent contraction may have important effects on viscera, interfering seriously with their functions.

It is well known that syphilis is a milder disease in females than in males, and experimental evidence suggests that the difference is due to female sex hormones.

Symptoms.—For convenience of description, syphilis is usually divided into four stages: the primary comprising the lesions occurring at the sites of inoculation; the secondary or generalised lesions; the tertiary or localised lesions, usually occurring much later, after a period of quiescence; and the quaternary or the lesions affecting primarily the parenchyma of the central nervous system. The division is only empirical, and it must be remembered that one stage may merge into or overlap another.

PRIMARY STAGE.—The incubation period varies from a minimum of about 10 days to a maximum of about 90, with an average of 3 to 4 weeks. A small papule (*the primary chancre*) then appears at each site of inoculation (commonly only one or two, but sometimes more), and quickly enlarges to a round or oval sore about the size of a threepenny bit, a sixpence, or larger; the centre usually becomes eroded, or perhaps more deeply ulcerated, and the broken surface is surrounded by a dull-red areola varying in width from half to 2 or 3 mm. Beyond the confines of the eroded area the tissues are infiltrated, feeling tougher than the corresponding tissues on the other side of the part. This induration, which gives the lesion its common name of *hard chancre*, becomes more and more pronounced until in the case of some primary sores, it feels as if there were a button embedded in the tissues. The sore does not bleed easily when scraped, but serum oozes freely from it, and this serum usually teems with syphilitic organisms. The sore is comparatively painless.

Individual features vary with the site. Thus, the most indurated are those on the under-surface and mouth of the prepuce in males, and the labia, posterior commissure and *portio uteri* in females. In the case of a sore at the reflection of the prepuce on to the *corona glandis*, when the prepuce is retracted, the lesion flicks over like a plate turning on its edge. A sore at the mouth of the prepuce often converts it to a fibrous ring. Induration is easy to elicit in sores affecting one wall of the *fossa navicularis*, which then feels as if a plate were embedded in it. In primary sores of the glans itself induration is difficult to elicit owing to tightness of the tissues, but the sore is easy to recognise by its dull-red areola, even contour, eroded centre, and indolent progress. Rarely a primary sore has been reported deep in the urethra, the diagnosis being made by urethroscopic examination together with the discovery of *S. pallida* in the scanty urethral discharge. Primary sores of the skin are dark red, covered with a dark scab, and tough in consistency. Ulceration is usually more marked in sores affecting the undersurface of the prepuce, the skin at the peno-scrotal angle, the tissues around the nails, the lips and the tonsils. Almost all primary sores are comparatively painless, but when affecting the terminal phalanx of a finger or thumb they may be exquisitely painful, and thus may be mistaken for whitlow. The primary sore affecting the prepuce, the skin of the penis, or (especially) the female labia may be accompanied by a toughly indurated oedema of the affected parts, which become somewhat livid; the same condition may affect the uterine cervix.

The course of the primary sore varies greatly. In some cases the lesion is fleeting, and its apparent triviality may lead to neglect of treatment; the history of a substantial proportion of cases of tabes and general paresis is that the initial lesion was either unnoticed or was very trivial. The ordinary sore which remains untreated lasts for a month or longer, and long after the

erosion has healed over, a button of indurated tissue may remain to mark the site; syphilitic organisms have been found by histological examination in such scars many years later, and weeks or months after it has healed the sore may break down again. When a sore is infected by secondary organisms, ulceration is a more prominent feature, and in rare instances it becomes phagedenic. In such cases the surrounding tissues very rapidly become black and necrotic, and the resulting loss of tissue may involve large portions of the external genitals.

Shortly after the appearance of the primary sore the nearest lymph glands often become painlessly enlarged, and in the case of the penis the lymphatics running from the sore can frequently be felt below the skin. The affected glands may reach a large size, bulging out the overlying skin; and this, with the fact that there is no reddening of the skin or other sign of acute inflammation, often gives the clue to the nature of the sore on which it depends. In females if the inguinal glands escape, owing to the internal situation of the sore, enlarged pelvic glands may often be found by palpation through the vagina against the ischiac bone. Syphilitic buboes do not usually suppurate, but may do so if the sore has become contaminated by secondary organisms, so that suppuration should not weigh heavily against a diagnosis of syphilis. A week or so after the local lymph glands have begun to enlarge there is universal adenitis, which can be appreciated by palpation, particularly of the epitrochlear, axillary and cervical glands.

About this time, or when the sore is about 15 days old, the blood serum often for the first time gives positive Wassermann and other serum reactions, such as the Kahn, Kline, Meinicke, Müller, Sachs-Georgi and Sigma. The last six depend on directly visible changes which occur in mixtures of syphilitic serum and diluted extract of heart muscle prepared by special methods. The percentage of cases in which the Wassermann and other reactions are given increases with the age of the disease until the outbreak of the skin lesions which manifest the next or secondary stage. Practically 100 per cent. of patients in the secondary stage are positive.

SECONDARY STAGE.—Usually, but by no means always, a generalised roseolar rash appears three to six weeks after the sore. It generally starts on the sides of the trunk as pinkish spots, varying in size from a split-pea to a little-finger-nail, which deepen in colour with age to a dull-red or somewhat brownish tint. At first they may be difficult to see, but become more manifest after the patient has been stripped for a few minutes. Sometimes the spots are slightly raised and urticarial in appearance (*roseola urticata*). The eruption spreads gradually over the trunk and limbs, and fades in a few weeks, leaving little or no staining. It may recur at a later period, and the spots are then annular or ring-like.

After the fading of the first roseola, a peculiar change in the distribution of the pigment may occur, especially on the necks of brunettes. The neck becomes generally discoloured, or looks dappled (*syphilitic leucodermia*), as if the pigment had been washed out of a number of circular areas, each about the size of the end of a finger-tip, and had collected at the margins. An unusually high proportion of cases of syphilitic leucodermia have been found to have syphilitic changes in the cerebro-spinal fluid.

The *papular* eruption follows closely after the roseolar, and takes a number of different forms, the commonest and usually the earliest being dome-shaped,

dull-red papules distributed over the trunk, limbs and face. Most are about the size of a lentil, but amongst the smaller papules may be many larger ones, sometimes even the size of a silver threepence. The papule feels tough and when squeezed between finger and thumb appears glistening white, while its surface cracks slightly. Variations of the ordinary papular eruption are the papulo-squamous, squamous, papulo-pustular and pustular. In the *papulo-squamous* a large proportion of the papules are covered at their centres by loose scales. The *squamous* syphilide is a papular eruption in which scaling is a still more prominent feature. In the *papulo-pustular* syphilide the centre of the papule necroses, and looks rather like an acne spot. When the whole papule breaks down, a pustular syphilide results and this may resemble a varicellar or a variolous eruption. A more severe and malignant form is the cethymatous type, in which the papule breaks down quickly, and the underlying tissues are eroded or ulcerated. As the destruction of tissue extends, the secretion dries to a crust. This may become heaped up by the deposit of successive layers, and the result is a blackish crust, shaped like a limpet (*rupia*).

Peculiar appearance of the papular syphilide in different situations.—

Between the buttocks, on the lateral surfaces of the scrotum, on the labia, and on the upper and inner sides of the thighs, the papular syphilide often becomes very prominent and wart-like, with a greyish-white appearance; these syphilides are called *broad condylomata*; the whole of the contiguous surfaces of the buttocks may be covered with them. On the scrotum this syphilide often looks like white slightly raised damp rings with brownish centres; these *moist papules* are best displayed by stretching the skin. Between the toes, under the pendulant mammae, and in almost all moist situations, papules tend to run together, and a moist, pinkish-red surface, fringed with loosened epithelium, is left. Condylomata and moist papules generally exude serum freely, and the discharge is rich in *S. pallida*. On the palms and soles the papules appear as flat or slightly raised spots, varying in size from a split-pea to a sixpence. They scale easily, leaving collars of loosened epithelium surrounding the shining papules; sometimes the lesions run together into large plaques traversed by weeping fissures. The finger-nails may show characteristic changes, more especially in the recurrent secondary stages. The end of the finger becomes pinkish-red and bulbous, and at the reflection of the skin on the nail are weeping granulations. The nail becomes brittle and lustreless and is shed. The papular syphilide may be well marked on the forehead, following the margin of the hair (*corona veneris*), and it is often possible to find many papules in the hairy scalp. On other parts of the face, especially about the naso-labial fold and the chin, the papules are often set in rings. In some cases the facial lesions may be prominent, especially at a naso-labial junction, appearing like condylomata; on account of its similarity to yaws this condition is called a *frambsiform syphilide*.

The small *follicular syphilide* usually appears later than the lenticulo-papular. It occurs in small clusters of minute brownish papules, often thickly distributed on the back. The affected areas, which may be as small as 1 cm. across, have a goose-skin appearance and the part generally looks as if it had not been properly washed. The *lichenoid* syphilide, also a late secondary manifestation, occurs as small flat red elevations a few millimetres across, often polyhedral.

Recurrent papular eruptions.—Recurrences of the papular eruption tend to be much more limited in distribution. A common form, the *corymbose* syphilide, appears as one or only a few rather densely packed groups of papules from 1 to 3 inches or more in diameter. In some cases in the centre of the group is a large papule and around it, separated by a zone of healthy skin, a crowd of smaller papules. The chief sites are the extensor surfaces of the arms, the shoulders, back and abdominal wall. Sometimes the recurrence is a single papule as big as a shilling; it may occur on the genital area and be mistaken for a primary sore.

The *hair* is shed to a varying degree in the secondary stage. In most cases the thinning is not particularly noticeable; in others the fall is patchy, giving the back of the head a moth-eaten appearance; and in a few the patient may become temporarily bald. The beard and eyebrows may participate in these changes.

The syphilitic eruption in the mouth and throat.—Before the rash appears on the body the soft palate may become erythematous. Other lesions of the mouth usually make their first appearance at the time of the papular syphilide of the skin. On the mucous surface of the lips and the pillars of the fauces the early syphilide is a greyish-white patch (*mucous patch*) edged with a pinkish-red areola, which marks it off from the surrounding mucous surface. On the pillars of the fauces the appearance is that of a snail-track creeping up over the pillar on to the soft palate. On the tonsil the lesion tends to ulcerate rather deeply. The mucous patch on the lip is usually round or oval and, if it crosses the angle of the mouth, is fissured. On the sides of the tongue fissuring and ulceration are more pronounced, but on the under-surface there may be condylomata, while on the dorsum are pink, bald spots, the pile of the tongue having been rubbed off at each papule. The discharge from these lesions teems with syphilitic organisms, and is very contagious. Papules can also be seen in the nose, on the septum and the floor. In the larynx, by suitable examination, they can be seen chiefly on the epiglottis and aryepiglottidean folds; they are apt to become eroded and ulcerated, causing the husky voice often heard in syphilitic patients. As these lesions of the mouth and throat are more apt to recur in uncured cases than are those of the skin, it is very important to examine the mouth thoroughly in a possible case of syphilis.

Other mucous membranes.—Mucous patches also occur on other mucous membranes, such as those of the labia, just within the vagina, at the posterior commissure, the cervix, just within the anal canal, and on the glans penis and the mucous surface of the prepuce. Usually these are eroded and appear as sharply defined lesions against the background of normal-looking mucous membrane. On the genitalia, especially on the glans, they are quite often diagnosed as primary lesions, but this error can usually be avoided if it is remembered that not all sores on the genitalia are primary chancres.

Joints and bursæ are not often affected in secondary syphilis, but occasionally an *acute synovitis* occurs. It is fairly painful, and usually worse at night. A more indolent form of synovitis causes swelling without pain or great limitation of movement. The tendon-sheaths may be affected similarly, and the tendency to formation of adhesions may lead to permanent limitation of movement. Mild *periostitis* and osteocopic pains, worse at night, may occur in the secondary stage or even before any rash appears, but bone affections are commoner in the tertiary.

Epididymitis occurs in a very small percentage of cases, usually in the form of small nodules, varying in size from a pea to a small marble, in the *globus major*.

Thrombo-phlebitis, in the form of painless nodules in the superficial veins, particularly in the legs and resembling *erythema nodosum*, sometimes occurs.

From about the sixth month, or even earlier, the patient may develop symptoms pointing to syphilitic disease of the *central nervous system*, which are dealt with elsewhere. It is well to remember that in over 30 per cent. of cases in the secondary stage changes in the cerebro-spinal fluid indicate invasion of the central nervous system, though only a small proportion of these cases show clinical signs of nervous disease; this fact should be borne in mind when eventually tests of cure are being considered.

Constitutional symptoms.—*Fever.*—Even in the incubation period, rigor followed by some degree of fever and pains in the limbs may occur. In some cases, towards the end of the primary stage, or on the outbreak of the rash, the patient's temperature may become irregular, the pyrexia being intermittent, continuous, or remittent, and accompanied by some constitutional disturbance. In rare cases the fever and constitutional symptoms may be more prolonged and pronounced, and if no rash appears, the symptom-complex may be very puzzling. Its association with generalised adenopathy should arouse suspicion. Sometimes, just before the outbreak of the eruption, and during the early part of the secondary stage, the limbs ache and there may be definite lightning pains, which lends support to the idea that all these symptoms may possibly be due to meningeal involvement and irritation. In the early secondary stage also, headache may be severe, and may not improbably be due also to meningeal involvement.

Anæmia.—The red cell count may be slightly reduced, to between 4,000,000 and 5,000,000, and the colour index be as low as 70 per cent. In the early stages the white cells may reach 20,000 per c.mm. In early untreated cases the increase is due to polynuclear leucocytes, but under treatment these give way to lymphocytes, which may constitute 65 per cent. of the total; this lymphocytosis may persist for months. In rare cases the anæmia may be much more severe, Müller having reported one with a blood state resembling that found in pernicious anæmia.

TERTIARY STAGE.—There is no sharply dividing line between the secondary stage and the tertiary, since the earliest tertiary lesion, the tubero-serpiginous, is merely a collection of large papules, which are more deeply embedded, and tend more to ulceration than the papules of what is called the early secondary stage.

The *tubero-serpiginous syphilide* occurs in one or more isolated areas of the skin as a collection of skin gummata, each about the size of a pea, often running into one another to form a more or less continuous, brownish-red ridge, arranged in roughly concentric circles, or arcs of circles, or as a snake-like line of varying length. The affected area is very often one that is exposed to injury or constant friction; it may be as small as a finger-nail or larger than a hand. The individual gummata may degenerate only so slightly as to produce some scaling, or may ulcerate more deeply and become crusted. The lesion extends centrifugally by the development of more gummata, and leaves in its wake a reddish-stained area in which are supple, papery scars, showing well the concentric distribution of the lesion. Sometimes the nodules do not

resolve as the lesion extends, and a red nodular plaque of indurated tissue is formed. On the palms the lesion may be scirpiginous as described above, or affect chiefly the folds, which become fissured. In some ulcerative cases extension is more rapid than healing, and a large patch of small skin ulcers may be left in the wake of the advancing arcs of new lesions. Very rarely, and then mostly when situated close to the angles of the mouth, or at a nasal orifice, the ulcer may become phagedenic, causing extensive destruction of tissue.

Gummata of the subcutaneous tissues and muscles grow up as indiarubbery lumps which vary in size from a shrapnel bullet to an orange, or larger. They are painless, quietly expanding growths, which tend to break down in the centre, leaving clean-cut ulcers with tough, wash-leather sloughs occupying the bases. Sometimes the affected muscles are diffusely infiltrated, and much deformity results when the degenerated tissue is replaced by scar.

The *joints, bursæ and tendon-sheaths* are not often invaded in tertiary syphilis. The parts affected are, again, those most exposed to stress and strain, such as the knee-joint and the prepatellar bursa. The swelling is non-inflammatory, of soft rubbery consistence, and follows the lines of the affected joint, bursa or tendon sheath.

The *bones* are affected in tertiary syphilis in different ways, and in each of them the affection is commonly accompanied by boring or gnawing pains worse at night (osteocopic pains). In the long bones the most usual manifestation in acquired syphilis is a localised gumma which either ossifies and remains as a boss on the bone or breaks down in the centre, leaving either a depression ringed with ivory-hard bone, or an ulcer. If the process begins deeper, the local swelling may not be so obvious and, eventually, with discharge of the necrotic contents, one or two fistulous openings lead to the interior of the bone. Diffuse osteitis and periostitis are not so common in acquired as in congenital syphilis. A sign of congenital syphilis in adolescents and adults is the *sabre-scabbard tibia* resulting from diffuse periostitis in earlier years; the bone is thickened from before backwards, and its anterior crest is curved with its convexity forwards, giving the bone the shape from which the condition derives its name. Of the long bones, the most commonly affected in acquired syphilis are the clavicle (sterno-clavicular joint), sternum, ribs, tibia and femur; but no bone is immune, and the process is particularly apt to affect one which has received a blow or other injury. Syphilitic dactylitis is very uncommon. Usually the proximal phalanx is affected, and a quiet, painless swelling results. Sometimes a sinus forms and the bone becomes rarefied. The whole bone may become permanently thickened, or absorption may result in shortening. The cranial bones tend especially to become carious under gummatous infiltration, and some of the worst mutilations result from syphilitic caries of the bones of the nose and palate. After a period of ozæna the bridge of the nose may fall in, or a large perforation suddenly appear in the hard palate. The process may spread to the skin and most disfiguring ulceration of the face ensue. Gummata of the cranial vault may start in the inner or the outer tables of the affected bones. In the latter case, unless the resulting swelling is absorbed under treatment, a circular or perhaps a horse-shoe- or trefoil-shaped ulcer is formed with an ivory-hard ridge. The skull may be perforated, but usually by then the cranial cavity has been shut off. If the inner table is first affected, irritative and pressure symptoms result. Vertebral gummata are rare;

according to their situation they may cause retro-pharyngeal, lumbar, or iliac abscesses. Rarely they may cause pressure on the cord.

The *mouth and throat* often suffer severely in tertiary syphilis. Gumma of the tonsil is followed by ulceration. The soft palate may be strewn with a number of pea-like nodules which often ulcerate and result in all grades of deformity. Perforation, usually at the junction with the hard palate, is common, and sometimes the soft palate becomes adherent to the posterior pharyngeal wall. Perforation of the hard palate may result from gummata commencing on the mouth side.

In the *tongue* discrete gummata may eventually reach the surface and cause deeply punched-out ulcers. In a form analogous to the tubero-serpiginous syphilide a number of pea-like nodules affect a moderately large area of the tongue. This becomes swollen and tender, but, unlike the diffuse glossitis mentioned below, is very amenable to treatment. A much commoner manifestation of tertiary syphilis of the tongue is diffuse glossitis, which may be deep or superficial. The affected portions are swollen and the surface is smooth, hard, inelastic and usually covered by a bluish-white pellicle (*leucoplakia*). On retrogression, the tongue becomes cut up into numerous islands by fissures of varying depth. The tongue is tender, and intolerant of spices and hot food.

The insides of the cheeks opposite the gap between the upper and lower teeth often show leucoplakia as a white ridge cut up herringbone fashion, which is quite characteristic.

Tertiary syphilis of the *testicle* occurs in two forms, diffuse interstitial and nodular. In the former the testicle slowly enlarges and becomes heavy but remains quite smooth; the testicular sensation is lost. In the nodular form, often engrafted on the diffuse, gummata project like bosses from the surface of the testis. The epididymis is usually not palpable, and commonly the cord is moderately thickened. There may be a hydrocele. The gummata may break down, giving rise to a form of *fungus testis*. Tertiary syphilitic *epididymitis* is rare, and syphilitic *prostatitis* more so. It is interesting that, although histological evidence of involvement of the body of the testicle can be found in almost every case, changes in the ovaries are very rare.

Fever occurs in some cases, and its dependence on syphilis has been shown by its response to anti-syphilitic treatment. It has been seen mostly in hepatic syphilis. As examples of the type of fever and the importance of an investigation with syphilis in view in cases of obscure pyrexia, the disease has been mistaken for rheumatic fever in those cases of the former in which there was periostitis in the vicinity of joints; it has also been mistaken for tuberculosis.

Diagnosis.—PRIMARY STAGE.—It is axiomatic that every genital sore and every non-malignant sore elsewhere on the body which is not easily accounted for should be examined for *S. pallida*. This should be done before any antiseptics have been applied, as they kill the organisms in the superficial layers and prejudice the success of the examination. The sore should first be cleaned with a swab and its edge scraped, or a fairly deep puncture made in its margin with the point of a scalpel or a vaccination lancet. The sore should then be squeezed and the serum collected after it has oozed for a few minutes. When the necessary apparatus is at hand it is better to examine the specimen at once by dark-ground illumination; if it has to be

sent away, the serum should be allowed to run into a capillary tube, only one end of which need be sealed. Alternatively a good method is to puncture the nearest enlarged gland and aspirate a little of the gland juice. A moderately stout hollow needle is run obliquely into the gland, and a few minims of sterile saline are injected into it. The gland is massaged and aspiration applied by a syringe.

Spiral organisms other than *S. pallida* may be seen in a specimen obtained from the genitals or the mouth. They are largely eliminated by taking care to clean the surface of the lesion before collecting the specimen. All coarsely spiral organisms should be excluded at once, and only three others need cause difficulty. A fairly fine spirochæte, with closely set spirals, often found in specimens from the genitals is about twice as thick as *S. pallida*, shines more brightly, has a slight rusty tinge, and spirals which are not so cleanly cut as those of *S. pallida*. Two spirochætes may be found in the mouth, both as fine as, or finer than, *S. pallida*. One is distinguished by the angularity of its turns, the other by its spirals being much more closely set, so that it looks like a piece of twisted silk.

Clinically, primary syphilitic sores are distinguished from others by the incubation period, colour, indolence, surrounding infiltration, comparative painlessness, slighter tendency to bleed, indolent enlargement of neighbouring glands, and the presence of *S. pallida*. The length of the incubation period is a guide only when the patient has not been exposed to infection for over 10 days.

A collection of *herpetic vesicles* on the penis is made up of minute, pin-head sized circles without induration, but usually irritable. *Chancroid* has an incubation period of only a few days; the sore is more inflammatory and undermined, often with a more irregular edge which is merely tipped with red and has no areola; it is excavated, rather than worn down. Chancroid may be accompanied by a bubo which tends to suppurate. A syphilitic bubo may, however, suppurate, so that it would be a mistake to exclude syphilis on the sole ground of suppuration. If the glands, though distinctly enlarged, showed no sign of active inflammation, it would be strong evidence in favour of syphilis. Since there may be a double infection, microscopical examination should be repeated at intervals until the sore has healed, and the serum should be tested at least monthly for 3 months.

Scabietic runs on the glans and skin of the penis are mound-like and not eroded or indurated.

Syphilitic chancres in parts of the body other than the genitals are often overlooked, mainly because syphilis is not thought of in those parts. A unilateral tonsillitis should arouse suspicion, especially if associated with painless enlargement of the submaxillary glands on one side. Similarly, the clue to the nature of a lip chancre may be given by the glands. Primary sores affecting the terminal phalanx of a thumb or finger often simulate whitlows; the syphilitic sore is more brawny, and remains so much longer after the sore has been lanced.

SECONDARY STAGE.—The maculo-roseolar syphilide is fairly easy to distinguish by the history of a primary sore with indolent adenitis; by the subcuticular, deeply grounded appearance of the spots, which first appear on the flanks, very rarely itch, and are pinkish or dull-red; and by the coincidence of positive serum reactions. Other erythemata are brighter red

and irritable, and often affect the backs of the hands. *Urticaria pigmentosa* may resemble a maculo-papular eruption, but the dark spots are not raised, and on rubbing the macule a wheal is formed. The serum may give a doubtful or even a positive reaction, but this is considerably weaker than that usually given by the blood of a patient with a secondary syphilide. *Schorrhæa* is more superficial and is more scaly, the scales being greasy. *Pityriasis rosea* is often mistaken for syphilis, but the lesions are brighter in colour and more irritable; they tend to become annular, with their centres covered by branny scales. *Ringworm* is more superficial and irritable, and the fungus can be found in scrapings from its border. *Tinea cruris* or *dhobie's itch* affects a triangle at the upper and inner part of the thigh; it is brighter red, more irritable, and quite superficial. *Drug rashes* are more inflammatory and irritable; they appear more suddenly, and are associated with a history of the patient having taken such a drug as copaiba, cubebs, antipyrine, quinine or belladonna. The eruptions of specific fevers are usually accompanied by more pronounced constitutional symptoms.

The ordinary dome-shaped papular syphilide is usually easy to distinguish from a non-syphilitic eruption. The indurated feel of the papule, its shining appearance when pinched, its readiness to scale, and its dull or pinkish-red colour are valuable diagnostic signs, as is also the association with mouth and throat lesions. The different appearances which a papular syphilide presents in different parts of the body, such as dry papules on the trunk and most areas of the limbs, moist papules on the scrotum, between the toes and in other moist, warm parts, and wart-like condylomata on the scrotum, contrast strongly with non-syphilitic dermatoses, which are true to type, wherever situated. The microscopic test should always be applied to the exudate from the lesion in any doubtful case, and very rarely fails, even with the papulo-pustular or the pustular syphilide. *Acne spots* are more inflammatory, and affect the upper front of the chest and between the shoulders behind, rather than the flanks, loins and limbs. Pus can usually be expressed from blind acne pimples when they are pricked and squeezed. *Molluscum spots* are white and umbilicated, while caseous matter can be squeezed from their centres. *Lichen ruber planus* is characterised by flatter, smaller, polygonal spots of a violet tinge and waxy covering; it is more irritable. *Psoriasis* is usually less indurated, more superficial, bleeds at a number of points when slightly scraped, and affects the extensor rather than the flexor surfaces of the limbs; the scales are more silvery, and in moist situations the rash remains true to type, contrasting with the syphilide, which here becomes sodden with the secretion that freely oozes from it. *Varicellar spots* are vesicular at one stage, more superficial and irritable. In *variola*, besides the febrile prodrome with backache, the spots are of uniform character and appear first on face and wrists. *Pemphigus vegetans* may superficially resemble condylomata, but no *S. pallida* can be found in the juice from the lesions, and usually unmistakable bullæ can be found somewhere about the body or on the limbs. *Syphilitic condylomata* are apt to be diagnosed as hæmorrhoids, but they are usually separated from the anal ring by some normal skin. *Ordinary papillomata*, or condylomata acuminata, are pedunculated. *Bromide* and *iodide* eruptions appear more suddenly, and are considerably more irritable. The deeper forms of pustular syphilide with considerable crusting, such as the superficial and deep ecthymatous, or the rupial, are distinguished

from ordinary *impetigo* by the darker colour of the crusts, the circular rather than linear shape of the lesions, and the greater degree of tissue destruction below the crusts. *Scabies* is often mistaken for a crusted syphilide, and vice versa. The individual scabietic lesion is easy to recognise, but the tendency is to forget that scabies and syphilis often coexist.

Secondary syphilitic mouth lesions are easily diagnosed by the characters mentioned. *Vincent's angina* may cause confusion, but there is no pinkish areola, and the microscope easily settles the diagnosis.

TERTIARY STAGE.—An indolent swelling, or an ulcer preceded by a swelling, the lesion being obviously deeply embedded in the tissues or breaking down in the middle (which contains a characteristically gummy material) and sclerosing at the margin, with a circular, crescentic or even sinuous contour, and brownish-red in colour, should always arouse a suspicion of syphilis. Denial of primary sore, or of secondary lesions, is of no importance, as they may never have appeared or have long ago been forgotten. The positive serum reactions may mislead, since by no means all ulcers in an old syphilitic are themselves syphilitic. On the other hand, negative serum reactions are rather strong evidence against tertiary syphilis. *Epithelioma* is perhaps more likely to be confused with tertiary syphilis when the lesion is in the mouth, but epithelioma has a considerably harder margin, and the edge is rolled, not clean-cut. A positive serum reaction may be a trap, as epithelioma is often engrafted on an old syphilitic glossitis. Ulcers on the legs resulting from *varicose veins* or *impetigo* may arouse a suspicion of syphilis. They are usually much less regular in contour and associated with more inflammatory or congestive manifestations. Syphilitic orchitis is easily distinguished from other conditions by the evenly smooth hardness of the testicle, the weight and the absence of testicular feeling. Syphilis of the viscera and of the central nervous system is dealt with in other sections of this work.

Treatment.—**PROPHYLACTIC.**—For males a good condom is a safeguard so far as the parts which it covers are concerned ; it also protects the female. It should be removed with care to prevent contamination of the parts by the discharge on it. Whether or not a condom is used it is advisable to disinfect, by washing well with soap and water and then steeping the parts for some minutes in $\frac{1}{1000}$ mercuric potassium iodide solution, or $\frac{1}{1000}$ mercury oxycyanide lotion. After this the parts should be anointed with an ointment, such as Gauducheau's, viz., mercury cyanide, 0.10 ; thymol, 1.75 ; calomel, 25.00 ; lanolin, 50.00 ; liquid paraffin, 10.00 ; soft paraffin to 100.00. Some mercury oxycyanide lotion $\frac{1}{1000}$ may be injected into the urethra after urination ; in urination the meatus should be alternately squeezed and released so that the urine first distends and then rushes forcibly from the urethra. In females the prior insertion of a suppository which foams on insertion into the vagina is most likely to prevent contact of the secretion with the mucous membrane of the vagina and cervix ; it should be followed by an antiseptic douche. Washing of the external genitals, followed by their inunction with ointment as above, should be practised as in males. It is important to remember that in all cases disinfection should be prompt and thorough.

Prophylaxis by ingestion or injection of anti-syphilitic remedies is not recommended, because it may only mask the symptoms for many months.

As any prophylactic measure may prevent only the appearance of the chancre, it should be followed by blood tests for at least 3 months,

Accidental infection of fingers, lips and other extra-genital parts is best prevented by avoiding contamination with fresh secretions from persons in the earlier stages. These should be warned of the risk arising from sharing table utensils, crockery, and house linen with others. They should not kiss others or talk directly into people's faces, and articles which they have used should be dipped in very hot water. A further precaution is to keep open lesions smeared with an antiseptic ointment such as the cream mentioned above.

CURATIVE.—The remedies most commonly employed for the treatment of syphilis are preparations of (1) arsenic, (2) mercury, (3) bismuth, and (4) iodine. The first three destroy the parasites; the last stimulate the removal of granulomatous tissue. At the time of writing another preparation has appeared which promises to rival the most potent we have and to be the means of shortening very materially the treatment of syphilis. This is *penicillin*, which in trials hitherto carried out has caused the disappearance of spirochetes from lesions, healing of lesions, both early and late, and the reversal of serum reactions in early cases in a manner quite as striking as that which follows the administration of the most efficient metallic remedies we have, and without any accompanying toxic effect. The optimum dosage has to be ascertained, but in the routine treatment of syphilis in the American and British Armies, 40,000 units are administered every 3 hours for 60 doses. It is known that in pregnancy it penetrates to the foetus in effective amounts. It remains to be seen whether it is a complete remedy for the disease, or whether, as proved to be the case with the arsenical preparations, it will require the assistance of the other remedies. It seems fairly certain, however, that it neither hinders the therapeutic effect of the metallic preparations nor enhances their toxic effects.

(1) *Arsenical preparations*

These are organic compounds in which the arsenic is trivalent or pentavalent. The trivalent are by far the most frequently used for the treatment of syphilis outside the central nervous system; the pentavalent compounds are used chiefly in syphilis of the central nervous system and in syphilis in infants.

(a) *Trivalent arsenical remedies*

These are by far the most efficient of the arsenical remedies for the treatment of syphilis outside the central nervous system and, beginning with the famous "606" or the Ehrlich-Hata remedy introduced to the public in 1910, have revolutionised the treatment of syphilis. There are now a large number of these compounds whose different trade names are apt to be confusing, but fortunately all except oxophenarsine are subject to Regulations under the Therapeutic Substances Act, under which, besides being required to satisfy certain tests for toxicity and therapeutic potency, each must bear on its label an official name according to its chemical constitution. The following are the principal remedies in this class:

(i) Arsphenamine, or the dihydrochloride of dioxy-diamino-arsenobenzene, which is the original "606," or salvarsan; it is sold under the trade names, Arsenobillon, Diarsenol, Kharsivan and Salvarsan; and it

must have an arsenical content not less than 30 per cent. and not more than 34 per cent. (ii) The disodium salt of (i), or sodium salvarsan; it contains about 20 per cent. As. (iii) Neoarsphenamine, or the sodium salt of dioxy-diamino-arsenobenzene-methylene-sulphoxylic acid, which is the original "914," or neosalvarsan; it is sold under the trade names Evarsan, Neokharsivan, Neosalvarsan, Novarsan, Novarsenobillon and Novostab; it must contain not less than 18 per cent. and not more than 21 per cent. As. (iv) Sulpharsphenamine, or the sodium salt of dioxy-diamino-arsenobenzene-methylene-sulphurous acid; it is sold under the trade names, Kharsulphan, Metarsenobillon, Myosalvarsan, Sulfarsenol and Sulphostab, and its arsenical content is the same as that of neoarsphenamine. (v) Arsphenamine glucoside, or Stabilarisan; the arsenical content of the dose stated on the label equals that of the same dose of neoarsphenamine. (vi) Silver arsphenamine. (vii) Neosilver arsphenamine. (viii) Oxophenarsine.

Each of the above preparations except oxophenarsine bears the name "arsphenamine" in its official designation, and this group will be referred to below as the arsphenamine preparations. Of the arsphenamine preparations, all but the diglucoside are in powder form, sealed, in stated doses, in glass ampoules containing a neutral gas. All the powders except the silver preparations are yellow. All oxidise and become increasingly toxic on exposure to air and must consequently be made up and administered as soon as possible after the ampoule has been opened. Oxidation in the ampoule, through a flaw in the glass, makes the powder become darker and sticky. Stabilarisan is in solution and ready for use when drawn from the ampoule. It must be used before the expiry date stated on the label.

Arsphenamine is therapeutically the most active of the arsphenamine preparations, but is little used outside the U.S.A. because of the complexity of its preparation for administration and of its greater tendency to cause serious reactions on the day of injection. Sodium salvarsan is not greatly used in English-speaking countries.

Neoarsphenamine is by far the most commonly used of all the arsphenamine preparations. In equivalent dosage it is less active than arsphenamine, but is more easily prepared for administration and causes less general reaction. It causes too much pain to be given as routine by the subcutaneous or intramuscular route, but when it is administered in this way it is therapeutically more active. This is probably because the subcutaneous route favours more the retention of the remedy in the body, thus giving better opportunity for the formation of the derivative which is believed to be the spirochæticidal agent.

Sulpharsphenamine was introduced by Lehnhoff-Wyld under the name of Sulfarsenol for injection by the intramuscular or deep subcutaneous route. It causes comparatively little discomfort when administered in this way. Being relatively stable, its action is inferior to that of neoarsphenamine when it is given intravenously, and even when administered subcutaneously its effect is barely equal to that of neoarsphenamine given intravenously. It is rather more apt than are the other arsphenamine preparations to cause blood dyscrasias.

Arsphenamine diglucoside is a convenient preparation in being ready for use when drawn from the ampoule, but its immediate effect in causing disappearance of *S. pallida* from the juice of early lesions is not so great as that

of neoarsphenamine in equivalent dosage. A dose of 0.45 g. of a good brand of neoarsphenamine will cause *S. pallida* to disappear from such lesions in 24 hours in over 75 per cent. of cases, but, in my experience, even 0.60 g. stabilarsan has failed in this respect in over 50 per cent. of cases. Whether or not this preparation makes up for its slower spirochætidal action by greater persistence is uncertain. Silver arsphenamine and neosilver arsphenamine are emery-coloured powders. They are more active but also more toxic than the others and are given in approximately half the dosage of the latter. They are useful as a change from neoarsphenamine but are not now greatly used in Great Britain.

Oxophenarsine—to give it its official name in the U.S.A. and that by which it will be officially designated in Great Britain if and when it becomes subject to the Therapeutic Substances Act—is a newcomer in this field, though originally tested by Ehrlich, is commonly known as arsenoxide. It is believed to be chemically identical with the spirochætidal derivative of the arsphenamine preparations formed in the body after their injection. It is m-amino-p-hydroxyphenyl-arsine oxide, and the only preparations of it that are available at the moment are the hydrochloride, sold in this country as Mapharside (in the U.S.A. as Mapharsen) and the tartrate which is sold under the name of Neohalarsinc. It is a stable compound which has acquired great popularity in recent years, especially in the U.S.A. and it seems to be almost the only arsenical preparation used in the American and Canadian armies. It has also been adopted recently in the British Navy, and is now the most preferred arsenical compound for the intensive treatment of syphilis, which is discussed below. Its relative efficacy is at present undecided. A common statement is that it is less toxic and more efficient than neoarsphenamine, and this statement is repeated from article to article without accompanying proof. It would appear, however, that in respect of immediate effects it is about ten times as toxic as neoarsphenamine, and the important question is whether it is ten or more times as potent therapeutically. The evidence seems to be clear that it is not, but detailed discussion of this question would occupy too much space here, and I must be content with saying that, after a very close and critical study of the evidence, I am convinced that, weight for weight, it is not more than four times as active therapeutically as is neoarsphenamine. It may be useful for the intensive forms of treatment in which three or more injections a week are given, because it is stable and is quickly excreted, but this is a very different matter from using it in the well-tried and tested prolonged systems of treatment which must remain routine practice until the evidence on the more intensive forms of treatment and on penicillin has become more decisive than it is at present. The dosage, administration and toxic effects of oxophenarsine will be discussed after those of the arsphenamine compounds.

Dosage of arsphenamine compounds.—Doses of the different preparations named vary greatly with circumstances and can be discussed here only in general terms, but guidance for treatment of individual cases will be found below in the discussions on toxic effects, on contra-indications, and on schemes of treatment. In a case of active primary or secondary syphilis it is reasonable to aim to bring about rapid disappearance of *S. pallida* from the juice of external lesions, and when there is no contra-indication in an adult male I start with 0.45 g. neoarsphenamine. If, in such a case, I have to begin with a

lower dose, it is with no illusion as to the effect on the spirochætes, and the injection is repeated much sooner than if the full initial dose had been given.

Administration and toxic effects of arsphenamine preparations

Intravenous route.—This is the most usual route. In the case of neo-arsphenamine the dose is dissolved in 2 to 10 c.c. distilled water. Silver-arsphenamines are dissolved in not less than 8 c.c.; stabilarsan is already in solution and requires no further dilution. The solution is drawn into a syringe, which is armed with a fairly fine needle (S.W.G. 22), any of it contaminating the outside of the needle is washed off in sterile water, and the point of the needle is inserted into a median basilic or other convenient vein, which should be distended as tightly as possible by fixing an elastic band round the upper arm and getting the patient to grasp a roller bandage. In making the vein-puncture the operator should look along the vein, and steady it with the index finger of the other hand laid on the skin below the site; the eye of the needle should look away from the skin, and its shaft be almost parallel with it. A pull on the piston causes blood to flow back into the syringe when the needle is properly within the vein. The rubber band may then be released, and the piston is *slowly* pressed home. After it has been emptied, a little blood is aspirated into the syringe, to clear the needle of any solution.

Deep subcutaneous and intramuscular routes.—As already mentioned, arsphenamine remedies have a greater therapeutic effect when administered subcutaneously or intramuscularly, but most cause too much pain, and practically the only one which can be employed for the purpose is sulpharsphenamine. The dose may be dissolved in distilled water, or in one of the glucose solvents containing local sedatives which are sold for the purpose. In either case as little as 1 c.c. may be used, but 2 c.c. of the glucose solvent seems to be more effective in preventing local reaction. The technique of intramuscular injection is described on p. 228. Deep subcutaneous injection causes less muscle reaction, and is usually preferable; it is given as follows: In the upper and outer quadrant of the gluteal region the skin and fat are pulled away from the underlying fascia, by grasping them with the thumb and fingers of the left hand, and a 1½ inches long needle (S.W.G. 20) is entered obliquely at the base of the pyramid thus produced. The needle is made to underrun the fat so that its point may scrape on the fascia overlying the gluteal muscles. The charged syringe is fitted to the needle and the injection given fairly slowly. The site is then massaged with a pad of lint.

Toxic effects of arsphenamine preparations.—*Local.*—An intravenous injection of any arsphenamine preparation may cause thrombosis of the injected vein; this is not serious, but precludes the use of the vein for subsequent injections. Escape of any of the solution around the vein causes agonising pain, and swelling and infiltration of the tissues, which may go on to sloughing. When it occurs the area should be infiltrated at once with a few c.c. of sterile 0·85 per cent. saline.

General.—All these compounds tend to damage capillary endothelium. In patients who have died as a result of arsphenamine injections, there have been found blockage of cerebral capillaries with small hæmorrhages around; hæmorrhagic nephritis; hæmorrhage into lung alveoli; submucous petechiæ and ecchymoses in the stomach and bowel; and, in a comparatively few cases,

degeneration of liver cells amounting to a condition like that found in acute yellow atrophy.

Clinically, toxic effects are manifested by one or more of the symptoms enumerated below. The list is a comparatively long one, but most of the symptoms are so mild, infrequent, or preventable as not to preclude the routine use of these remedies. In roughly chronological order they are as follows:

1. *During or immediately after the injection.*—(1) Vasomotor disturbances, also known as anaphylactoid symptoms or nitritoid crises; (2) urticaria; (3) syncope; and (4) pain in the gums and teeth.

2. *Following the injection usually in a few hours, and occurring generally on the same day.*—(5) Rigor, rise of temperature, and headache; (6) vomiting, diarrhoea, pain in the back and cramp in the legs; (7) herpes (labialis or zoster).

3. *At various times from a day or two to a month or longer after a single injection or a course of injections.*—(8) Albuminuria; (9) stomatitis; (10) chronic headache; lassitude; loss of appetite, weight and sleep; (11) erythema and dermatitis; (12) jaundice; (13) severe cerebral symptoms; (14) various blood dyscrasias; (15) polyneuritis; (16) increase of syphilitic signs and symptoms (Jarisch-Herxheimer reaction).

The *vasomotor symptoms* simulate those of anaphylaxis; they are very rare after deep subcutaneous or intramuscular injections. The face becomes flushed, and the tongue and lips may swell; there may be respiratory distress, and the patient may become unconscious. Often a severe attack is followed by more or less generalised *urticaria*. As a rule the symptoms last for about half an hour, but in rare cases recovery is not complete for a number of hours. Some patients are peculiarly susceptible. In others the symptoms may be produced by imperfect preparation of the remedy for injection or too rapid administration, as they depend on the physical state of the solution on entering the circulation. For prevention, all these remedies should be injected slowly, and retention of the tourniquet during the injection, as recommended by Sicard, is very effective. The treatment usually employed is to inject 10 to 15 minims of solution of adrenaline hydrochloride (1 in 1000) intramuscularly; in particularly susceptible cases when slowness of injection and retention of the tourniquet fail, it may be useful to inject the adrenaline some minutes before the intravenous injection, or to give sulpharsphenamine deep subcutaneously. A feeling of *faintness* during the injection, or immediately after it, may be merely a precursor of vomiting, or due to fear. Occasionally, however, it may be very severe, fatal cases having been reported. Usually syncopal symptoms yield to ordinary restoratives; in some very threatening cases immersion in a hot bath has been reported to have brought about rapid recovery. *Pain in the gums and teeth* is probably vasomotor. The *peculiar taste in the mouth*, of which some patients complain during the injection, is a very common symptom when concentrated solutions are given.

Rigor, rise of temperature and headache are commonest after the first injection. The temperature is only rarely over 101° F. and is of no importance unless it increases after each successive injection. *Diarrhoea* and *vomiting* are not frequent unless there has been an error in technique, or the patient has been indiscreet in his dietary. Usually these symptoms have all disappeared by the next day. They are prevented to some

extent by taking care that the patient has fasted for 2 hours before the injection.

Albuminuria very rarely causes any anxiety. *Stomatitis* is not often attributed to arsphenamine remedies, but these undoubtedly seem to increase the tendency to this complication which is manifested by patients on mercurial, or bismuth treatment. *Chronic headache, lassitude, etc.*, are symptoms of intolerance displayed by a few patients, and indicate the necessity of a rest from treatment.

Various *skin affections* may occur besides the urticaria and herpes mentioned above, and may be very serious. The mildest is some slight itching which quickly passes off. Another form is Milian's erythema of the ninth day. It appears from the seventh to twelfth day after the commencement of the treatment and within $\frac{1}{2}$ to 2 days of an injection. It is ushered in with a rapid rise of temperature, to 101° F. or higher, headache, backache, and sometimes vomiting and diarrhoea. The temperature is intermittent for a few days, and ends with a generalised scarlatiniform, rubeoliform, or polymorphic eruption, which fades in a few days with very slight or no desquamation. In its prodromal fever and the subsidence of a generalised rash without desquamation in a few days Milian's erythema differs generally from the more serious type described next. Although it is said that arsenical treatment can be resumed after subsidence of ninth-day erythema, it is well to be very cautious on this point. The most severe dermatosis is relatively uncommon. It starts as a punctiform erythema which quickly spreads over the body, is accompanied by most intense itching, and often then passes on to exfoliative dermatitis. The incidence of dermatitis depends largely on the intensity of the treatment. Generally speaking, a male adult of average build will tolerate 5 to 6 g. neoarsphenamine in doses of 0.45 to 0.75, or the equivalent of this in other arsphenamine remedies, spread out over a period of 63 days but if this period is shortened, the percentage of dermatitis increases noticeably. A careful look-out for signs of skin irritation will often supply timely warning of the idiosyncrasy and, by preventing the administration of more arsenic, will save the patient from a severe attack. The treatment of exfoliative dermatitis following arsphenamine injections is often troublesome on account of the generalised exfoliation and the local pustulation and eczema. If the attack is at all severe, the patient should be in bed and well protected. Calcium thiosulphate, or sodium thiosulphate, which is now sold for the purpose in ampoules containing the remedy already in solution, may be injected intravenously every other day in doses of 0.6 to 0.9 g. The injection of calcium thiosulphate often causes a generalised tingling and flushing of the skin, which alarms the patient but passes off very quickly. On intervening days an intravenous injection of 30 c.c. of a 30 per cent. solution of dextrose is valuable. The administration of liver, on the same principles as in anæmia, has been found beneficial. The diet should be simple, containing large quantities of bland liquids, and should not include eggs and meat. Locally, calamine lotion and liniment are soothing, and an occasional bran bath is valuable, but careful precautions should be taken against chill, as these patients are very prone to pneumonia.

Jaundice following injections of arsphenamine preparations appears to have become more common in recent years, and a voluminous literature on its ætiology has accumulated in all countries without any definite consensus

of opinion having been arrived at. In the very great majority of cases the type is mild, with clayey stools and highly coloured urine. Occasionally it is much more serious, with severe epigastric and hepatic pain, restlessness and delirium, followed by death. The changes found in these rare cases have been extensive degeneration of liver cells with round-celled infiltration of the supporting connective tissue, multiple subserous hæmorrhages, and frequently hæmorrhages into lung alveoli. Either type may occur during a course of injections or be delayed for many months afterwards. In this delay in onset, as in some other features, the fatal type of jaundice strongly resembles trinitro-toluene poisoning. This suggested that possibly the responsible factor was the benzene radicle of the arsphenamine compound, but in a recent inquiry it was found that the incidence of jaundice in cases treated with oxophenarsine compounds was just as high as in those treated with neoarsphenamine, though the dosage of benzene radicle in most of them was from a tenth to a fifth of that when neoarsphenamine was given. The exact part played by arsphenamine in the production of jaundice is uncertain, but the weight of evidence seems at present to favour a connexion between the amount administered as routine in a given time and the proportional incidence of jaundice, the more concentrated the course the higher being the percentage of jaundice. A feature of jaundice which has been noted in this and other countries is its tendency to occur in outbreaks which bear no apparent relation to changes in technique or brand of the remedy employed. This lends some support to the theory, held by some, that besides arsphenamine an extraneous agency (virus infection?) plays a part in the causation. This view is supported by evidence furnished by Ruge from the German Navy in which it was found that the incidence of salvarsan jaundice was closely parallel to that of ordinary catarrhal jaundice in the general population. More recently Salaman, King, Williams and Nicol, working in an army hospital, appear to have reduced the incidence of post-arsphenamine jaundice there by the employment of a very strict regimen of syringe sterilisation.

For the *prevention* of jaundice, the best practical measures appear to be good feeding, especially with proteins—the addition of 2·5 to 3 g. methionine, or of a pint of milk, to the daily diet is recommended by Beattie and Marshall (1944); precautions against oxidation of neoarsphenamine and similar compounds prior to injection; careful sterilisation of syringes between injections; and suspension of the treatment on the appearance of urobilinogen in the urine. A simple test for urobilinogen is to add to 5 c.c. of the *cold* urine 2 drops of Ehrlich's reagent, which is a 2 per cent. solution of p-dimethylamino-benzaldehyde in 5 per cent. hydrochloric acid. A red colouration, most easily seen when the specimen is viewed from the top over white paper, is an indication to stop the arsenical treatment for a few weeks, continuing with bismuth. For treatment of developed jaundice, besides alkaline stomach sedatives and a very light diet, daily intravenous injections of 30 c.c. of a 30 per cent. solution of glucose seems to help. There is also evidence that nicotine acid quickly stops the damage to the parenchyma caused by a variety of liver poisons.

Severe *cerebral symptoms*, with headache followed by mental confusion, epileptiform convulsions and coma, ending in death in a large proportion of cases, are now very rare under ordinary schemes of treatment, thanks to the moderate doses with which treatment is usually started. The symptoms

usually begin from 2 to 5 days after the second injection, but this is not an invariable rule. The autopsy reveals dilatation of capillaries and capillary hæmorrhages in the brain, which is œdematous, and sometimes hæmorrhagic nephropathy. Recent studies have shown that hæmorrhagic encephalopathy is more apt to occur in females than in males, and especially so towards the end of pregnancy. It is much more frequent in patients treated by the intensive methods which have become common, particularly in the U.S.A. in recent years, and is in fact the chief bugbear of this form of treatment. There cannot be any doubt also that, apart from the tragic cases with convulsions and coma which are commonly fatal, milder forms of encephalopathy have occurred in the form of severe headache and mental confusion in such a large proportion of cases treated by the intensive methods already mentioned as to make this form of treatment permissible only when the attainment of cure in a minimum period of time is the paramount consideration. As already indicated, the prognosis in cases with convulsions and coma is very grave, but sometimes removal of 15 to 20 c.c. spinal fluid, repeated on subsequent days if necessary, and bleeding to 15 to 20 ounces have seemed to be effective; the treatment should be instituted as quickly as possible after the onset of the symptoms.

Blood dyscrasias.—Three main forms of blood dyscrasias have been described, all of them very rare. They have followed sulpharsphenamine treatment relatively much more often than treatment by other arsphenamine preparations. They are thrombocytopenia, granulocytopenia, and aplastic anæmia. When any occurs it is often associated with dermatitis and with sore throat; the latter should be regarded as a warning sign. The symptoms and treatment of these dyscrasias are described elsewhere in the work.

Polyneuritis has been reported occasionally but must be extremely rare; I have seen only one case, a very mild one.

Jarisch-Herxheimer reaction.—A temporary effect of these, as of other antisyphilitic remedies, may be to increase the intensity of the syphilitic process. This may be important when an artery supplying some vital organ is already partly blocked; then the increase in severity of the process may result in a complete blockage which may be disastrous, as when a coronary artery becomes obstructed, or the patient develops hemiplegia, or dies of obstruction of the basilar artery. Such cases are very rare.

Neuro-recurrences.—Though not strictly a direct effect of arsphenamine treatment, paralyses of various cranial nerves, especially the seventh and eighth, became more common shortly after its introduction. These phenomena have been proved to be syphilitic recurrences and due to the small amount of treatment given in the early days of "606." Since then they have become very rare, when bismuth or mercury is given concurrently with the arsphenamine preparation in early cases.

Precautions recommended in treating patients with arsphenamine preparations.—In the case of sufferers from hepatic and advanced Addison's disease, in bleeders, and in those on the point of death from severe visceral disease of any kind, these remedies are contra-indicated.

In visceral disease of a less severe type than is mentioned above, in alcoholism, and when the patient is prone to such skin affections as eczema and severe seborrhœa, it is advisable to begin with a dose of 0.15 g. neoarsphenamine, and to increase the doses with caution; often in such

cases the injections of small doses may be given with advantage twice weekly. The same applies to patients suffering from syphilis of the brain, cord or viscera when there is reason to fear an exacerbation of the process. In diabetes mellitus it is necessary to be very cautious, as arsphenamine compounds increase the blood sugar, and the patient should be watched carefully by some one experienced in the administration of insulin. Every patient should be watched carefully through the course for signs of intolerance. This precaution may not absolutely prevent severe side-effects, but such as do develop will usually be much milder than when no notice is taken, for example, of an erythema, and the treatment is continued to the end of the course.

In all cases where intravenous injections are employed it is advisable for the patient to fast for 2 hours beforehand. Other methods of prevention of this and other toxic effects of arsphenamine consist in scrupulous care over technique.

Administration and toxic effects of the oxophenarsine compounds

These compounds are always given intravenously dissolved in 8 to 10 c.c. distilled water, as in the case of neoarsphenamine. Contrary to the case of neoarsphenamine, solution can be effected with agitation of the mixture, and standing tends rather to reduce its toxicity. The injection should be given quickly in order to avoid pain in the vein. The usual dose for an adult in the ordinary routine, prolonged treatment of syphilis is 0.04 to 0.06 gm., and it appears advisable to give this twice weekly instead of once, as is the common practice when neoarsphenamine is used for the treatment of average cases. The toxic effects are very similar in kind to those following administration of the arsphenamine compounds, except that vaso-motor symptoms and such-like immediate reactions do not occur. It has been claimed that jaundice is less when this class of remedy is administered, but this is decidedly not the impression gained from a study of statistics relating to large numbers of cases treated during the same periods in the clinics of this country.

(b) Pentavalent arsenical remedies

The principal remedies of this class used in the treatment of syphilis are (i) Sodium N-phenylglycineamide-*p*-arsonate (tryparsamide); (ii) 3-acetylamino-4-hydroxyphenyl-arsonic acid, or acetarsol (kharophen, orarsan, spirocid and stovarsol); (iii) the sodium salt of (ii); and (iv) the diethylamine compound of (ii) (acetylarsan).

Of these, tryparsamide is the most important because of its value in syphilis of the central nervous system. It is a white powder easily soluble in water, and the dose for an adult is from 2 to 4 g. (usually 3 g.) dissolved freshly in distilled water and injected intravenously once a week. A course lasts 10 to 12 weeks, and the interval between any two courses can be a month or six weeks. The main risk is of amblyopia, and for this reason the patient's eye-grounds should be passed by an ophthalmologist before treatment is started. If this is stopped on the first complaint of haziness of vision, permanent restriction of vision is very rare. Acetarsol was introduced in 1922 primarily as a prophylactic of syphilis for administration by mouth. Since then it has come into extensive use for the treatment of infants with congenital syphilis. Acetarsol-sodium and acetylarsan are given by injection; their

effects are mainly like those of acetarsol. Toxic effects are usually mild. Acetarsol can cause gastro-intestinal disturbance if taken too near a meal. Sometimes a mild erythema occurs and very rarely a severe dermatitis.

(2) *Mercurial preparations*

Mercury was formerly the sheet-anchor in the treatment of syphilis, but for routine work it has been largely superseded by bismuth, and it is now used mostly in cases where injections are impracticable, or by way of varying the attack on the disease. A great advantage of mercury, as of bismuth, is that it can be kept almost continuously in the circulation, so that the action is maintained after the arsphenamine has been excreted until it is safe to administer another such injection. To ensure the certain destruction of all the parasites, it seems to be necessary that an anti-syphilitic remedy should be present constantly in the body fluids for a long period.

Methods of administration.—The *oral method* is much favoured, but is apt to cause gastro-intestinal disturbance, and is exposed to the risk of failure through the patient's forgetfulness. I employ it only when the patient cannot take injections or inunctions and also when the patient cannot continue injections or remain under close observation. Favourite preparations are—(1) Hydrargyrum cum creta, grs. 1 to 2; (2) hydrargyri iodidum viride or flavum, gr. $\frac{1}{4}$ to $\frac{1}{2}$; (3) hydrargyri perchloridum, gr. $\frac{1}{8}$; (4) hydrargyri tannas, gr. 1 to 3; (5) pil. hydrargyri, grs. 1 to 3; (6) liq. hydrargyri perchloride, min. 30 to 60, often prescribed in a mixture with potassium iodide. The first five of these are usually given in pill form, often combined with a little opium, e.g. pulv. ipecacuanhæ et opii grs. 1 to 2, or extractum opii gr. $\frac{1}{8}$, to counteract the irritant effect, but it is better to prescribe the sedative separately, and regulate its dosage as required. I prefer to start with the iodide. A good plan of administration is to give courses of 6 weeks, gradually increasing the daily intake of mercury until slight signs of stomatitis appear, and then reducing the dose; of the yellow or the green iodide given in this way, an adult patient can usually take from $\frac{3}{4}$ to $1\frac{1}{2}$ grain daily. After the first and second courses rests of a week are given, and at the end of the third the interval is one month, after which the series of three courses is repeated. The length of time over which this treatment is prolonged depends greatly on the amount and character of the previous treatment.

Inunction.—This is a valuable method of administering mercury, but must be carried out by a skilled rubber, and has the inconvenience of soiling the skin and clothes. On successive days 5 to 10 g. of mercurial ointment (B.P.) are rubbed for twenty minutes into thighs, calves, arms, chest and back, a bath being taken on the sixth day and the cycle restarted on the seventh. The number of rubbings varies from 60 to 200 in a course, the length of a course depending on the patient's tolerance, which is judged by the state of the gums, the weight and the general well-being.

Intravenous injections are rapid in effect, but apt to cause toxic symptoms; they have the further disadvantage that the effect is not sustained, and they must be administered daily or every other day. The usual preparations employed are the cyanide and the perchloride, in doses of 1 c.c. of the 1 per cent. solution daily or on alternate days to a total of twenty or thirty in a course.

For *intramuscular injections* both soluble and insoluble preparations are employed. Among the *soluble* preparations are the biniodide (1 per cent. solution) in doses of 1 c.c., the bibromide, the benzoate and the perchloride. Their disadvantages are similar to those of intravenous injections.

The *insoluble* preparations most commonly employed are mercury in fine subdivision (inj. hydrargyri), calomel (inj. hydrarg. subchlor.) and mercury salicylate. Suspensions of these remedies ready for use can be purchased. The doses usually employed are: mercury, 1 to $1\frac{1}{2}$ grs.; calomel, $\frac{1}{2}$ to $\frac{3}{4}$ gr.; salicylate, $1\frac{1}{2}$ to 2 grs. Calomel causes more pain than the other two, but is far more active, and is probably the best for this purpose if it can be tolerated. Mercury salicylate is probably the least active of the three. The advantages of the insoluble preparations are that, on account of the slow absorption, enough mercury can be given in one injection to last a week and that the effect is sustained.

The technique of intramuscular injections is simple. The best sites are the upper and outer quadrant of the gluteal region and the upper third of the vastus externus muscle. A needle of S.W.G. 20, $1\frac{1}{2}$ inches long is introduced, almost to its full length, perpendicularly to the skin surface. The base is examined to see that no blood is oozing from it, the syringe is applied, the piston pulled upon to see that the needle point is still not within a vein, and the piston is then pressed home. The needle having been withdrawn, the site is well massaged with a ball of cotton-wool. Before an insoluble preparation is drawn into the syringe, the suspension should have been well mixed, either by stirring with a glass rod or by energetic shaking of the bottle.

Toxic effects of mercurial preparations.—These are stomatitis, nephritis, colitis, general malaise and dermatitis.

Stomatitis can usually be prevented by care. The patient's teeth should be set in order before starting the course, and he should brush his teeth night and morning; the tooth brush should be kept in an antiseptic solution, such as chloramine T., 0.5 to 1 per cent., or in an atmosphere of formalin. Potassium chlorate is useful, and may be incorporated in the dentifrice. If the gums become sore, the mercury must be stopped and more energetic treatment applied to the mouth. Lozenges of potassium chlorate to suck, and swabbing with peroxide of hydrogen followed by the application of a 10 per cent. solution of neoarsphenamine usually suffice to restore the gums to a healthy condition. An astringent mouth-wash should be employed and injections given of calcium or sodium thiosulphate. (See p. 223.)

Nephritis rarely results from the moderate doses of mercury now employed, but the irritant effect of mercury on the kidneys should be remembered in cases where these organs are already diseased.

Colitis is extremely uncommon as the result of the ordinary mercurial course of treatment. *General malaise* is apt to result from pushing mercury too freely, and it is always advisable to keep a close watch on the patient's weight and general condition. *Dermatitis* as a result of mercurial treatment alone is very rare.

(3) Bismuthial preparations

These were introduced by Sazerac and Levaditi in 1921, and have now largely supplanted mercury wherever the intramuscular, or deep subcutaneous, route of administration of a heavy metal is practicable. Bismuth is tolerated

better than mercury, and in doses which can be administered with at least equal safety, a course of bismuthial injections goes farther towards eradicating the disease than does a corresponding course of mercurial injections. Some workers assert that bismuth is equal in effect to the arsphenamine preparations, but the majority opinion is that it should be used in conjunction with these, in substitution for mercury.

Bismuth is at present administered almost exclusively by the intramuscular or the deep subcutaneous route, and the number of preparations is legion. They are best classified on the basis of rapidity of absorption as follows: (a) watery solutions; (b) solutions in oil (lipo-soluble preparations); (c) suspensions of insoluble compounds in a watery medium; and (d) suspensions of insoluble compounds in an oily medium. The comparative rates at which these different classes of bismuthial preparations are absorbed are in the above order.

Watery solutions are not greatly employed now, because they are more rapidly absorbed than is usually convenient; on account of rapid absorption, their toxic effects may approach those of preparations given intravenously, a route which is practically never used. For this reason they need not be considered further.

Oily solutions contain organic, lipo-soluble compounds dissolved in oil. In absorbability they are stated to be a useful medium between watery solutions on the one hand and insoluble suspensions on the other. The following are examples of these preparations of which it is unnecessary to state the chemical formulæ (the bismuth content per c.c. is stated in brackets after each): Bivatol (0.035 g.); Cardyl and Neocardyl (0.05 g.); Neo-olesal (0.03 g.); and Stabismol (0.1 g.). Their rate of absorption makes it advisable to give the weekly dose (see below) in two injections at a 3- to 4-day interval.

Insoluble suspensions are the most commonly employed preparations of bismuth for anti-syphilitic treatment, and this class contains the only three recognised by the British Pharmacopœia, namely, inj. bismuthi, inj. bismuthi oxychloridi and inj. bismuthi salicylatis. A number of insoluble salts of bismuth are used, and they are sold under a large number of names, of which the following are examples arranged according to their chemical construction. (a) Precipitated bismuth. Preparations: inj. bismuthi, B.P. (bismuth in a dextrose solution with cresol), and Bisglucol; both contain 0.2 g. Bi. per c.c.; and Bicrool (0.15 g. Bi. per c.c.); (b) Bismuth oxychloride. Preparations: inj. bismuthi oxychloridi, B.P. and Bisoxyl, both of them watery suspensions containing 0.08 g. Bi. per c.c.; Chlorostab, a watery suspension, two preparations with, respectively, 0.16 g. and 0.20 g. Bi. per c.c.; (c) Bismuth salicylate. Preparations: inj. bismuthi salicylatis, B.P., a 10 per cent. suspension of the compound in olive oil with camphor and phenol; Bisantol; Bismosan; Bismogenol, all oily suspensions; all this class contain about 0.06 g. Bi. per c.c.; (d) Bismuth hydroxide. Preparation: Casbis, Muthanol, and Spirillan, oily suspensions containing about 0.08 g. Bi. per c.c.; (e) Iodo-bismuthate of quinine. Preparations: Biquinyl; Bismosalvan; Quinby; Quinostab; Rubyl; Vijochin, all oily suspensions containing about 0.02 g. Bi. per c.c.

Toxic effects of bismuth.—The chief toxic effects are on the mouth and the

kidneys, but they may sometimes be seen in disturbances of the bowels, in the nervous system, and in the skin. As regards the mouth the first sign is a slaty-blue line on the margins of the gums, often first just behind the incisors and adjoining any unsound teeth. The blue line is inconvenient only because it is a tell-tale, and it is not an indication to stop the treatment. At the same time it is a rough guide to the speed of absorption, and if it appears early in the course of treatment, a particularly close look-out should be kept for signs of irritation of the buccal mucous membrane. These develop in the form of aphthous stomatitis, which may go on to cancerum oris if the administration of the bismuth is not stopped. The treatment of bismuthial stomatitis is on the same lines as for that due to mercury. The bismuth line persists for many months after the administration has ceased. *Albuminuria* is uncommon, but its possibility is an indication to test the urine periodically. *Gastro-intestinal disturbance*, in the form of pains, constipation, or diarrhoea is uncommon, as are also *restlessness*, *insomnia*, *rheumatic pains*, and *general depression of spirits*, all of which are mentioned only because their relation to the administration of the drug may not be recognised. *Skin disturbances* of many kinds have been described, even exfoliative dermatitis and purpura, but the latter are very rare. The commonest is in the form of patches of seborrhœic dermatitis on various parts of the body. It gives no trouble apart from anxiety in the patient's mind, and does not usually call for suspension of the treatment.

Choice of bismuthial preparations.—In syphilis with active external manifestations and when there is no contra-indication in the nervous system, the heart, and great vessels or other internal organs, we aim, in the present routine treatment, at complete eradication of *S. pallida* by attacking it over a long period with two types of remedy, namely, arsphenamine and heavy metal, the latter being either mercury or bismuth, of which bismuth is now almost always preferred. In this combination the arsphenamine compound rapidly stops the activity of *S. pallida*, and each injection of it deals a heavy blow at all accessible spirochætes, but the attack is not maintained; the dose of the arsphenamine preparation is quickly excreted, and for a considerable portion of the interval between any two injections, and still more between any two courses of injections, the arsenical remedy is not in action. In these circumstances it is conceivable that spirochætes not hitherto destroyed by the arsphenamine remedy, perhaps because of their entrenchment behind barriers of fibrous tissue, would have an opportunity of recovering if the attack were not maintained by another agent. This is the rôle of the heavy metal, an effective concentration of which can be maintained in the tissues for long periods. It will be understood from the above that, if an arsphenamine preparation is being employed in the treatment of the types of syphilis mentioned, one does not look to the bismuth for speed, but for persistence of action, and a preparation is needed which is absorbed slowly but steadily throughout the intervals between injections; this requirement is met by the use of a suitable insoluble compound. In the choice of such a compound, I am influenced by clinical experience and by reports of research on absorbability of different preparations, especially those of Lomholt, and prefer a compound such as the oxychloride suspended in a watery medium to either of the other two B.P. preparations. In some cases I have been convinced that when I have injected precipitated bismuth it has not been

absorbed at all satisfactorily, and excretion experiments which show that a higher percentage of a small dose than of a large one are absorbed in a given time argue against the employment of such a concentration of bismuth in the suspension as that in the *injectio bismuthi*, B.P. Between the salicylate or any of the other insoluble salts and the oxychloride there may possibly be little to choose, but Lomholt's experiments on absorption certainly showed that, other things being equal, a more rapid absorption would follow injection of a watery suspension than that of an oily one, such as *injectio bismuthi salicylatis*, B.P. On the other hand, the oxychloride is pure and stable and in watery suspension, provided it is not too finely powdered (particles of 3 to 5 μ dimensions are suitable), it is absorbed at a satisfactory rate without causing undue discomfort. This work confirms the favourable impression I have formed of the oxychloride in watery suspension in an experience of more than twenty years.

A quicker absorption of an insoluble compound is secured by giving the weekly dose in two injections at an interval of 3 to 4 days, or by dividing the dose between two sites injected at one sitting. In some cases it may not be possible to employ an arsphenamine preparation at all, or only in less than efficient dosage, and one has to depend more on the bismuth to stop the spirochætal activity quickly; in such a case one may give one of the oil-soluble preparations twice a week.

It will be judged from the above that usually an insoluble compound is injected about once a week, and a soluble one, two or three times. One insoluble compound, however, the iodo-bismuthate of quinine, which is not greatly used in early syphilis, but is valuable in cardio-vascular and neuro-syphilis, contains such a low percentage (20) of bismuth that the dose is contained in a large volume; consequently when employing this compound it is customary to give the weekly amount of bismuth in two injections. This compound is absorbed rather more quickly than most others in the insoluble class. In certain cases one may have reason to fear that the patient might become seriously intolerant, and it may not be desirable that the remedy should continue to be absorbed for long after suspension of the treatment. It would then be advisable to proceed cautiously with an oil-soluble preparation.

In average cases of primary and secondary syphilis I give bismuth concurrently with arsphenamine preparations, believing that when the latter are used alone at the commencement and in such doses as effectually to stop the interaction between parasite and skin, there is a much greater likelihood of the parasite getting a footing in the central nervous system. In this matter of concurrent arsphenamine with bismuth and of alternating arsphenamine courses with bismuthial ones, there is a difference of opinion amongst syphilologists, probably the majority in Great Britain believing in the concurrent plan. My own views are based largely on the facts that in the early days of arsphenamine treatment, when great reliance was placed on the administration of "606" in full or nearly full doses without the concurrent administration of mercury, syphilitic neuro-recurrences were common, and that in more recent years in certain clinics where the first course of treatment consists entirely of arsphenamine or neoarsphenamine in such doses as we know rapidly bring about the disappearance of *S. pallida* from the secretion of superficial lesions, the incidence of such neuro-recurrences has also been high. Certain

clinics in which the alternating plan is followed have not had this experience, and the explanation of the difference may lie in the dose of the arsphenamine preparation. If the dose of arsphenamine used alone in a first course given to an early case of syphilis is not so high as that mentioned above, it may be that the interaction between skin and parasite continues, and so evokes an immunity response which prevents the spirochaete from stimulating a big enough reaction in the meninges to cause symptoms. It is interesting that in the intensive forms of treatment employed extensively in the U.S.A., after much experimenting exclusively with arsenical remedies, the concurrent administration of bismuth is being more and more extensively adopted, on recommendations by Eagle which are based on systematic animal experimentation.

(4) *Iodine preparations*

These promote the resolution of syphilitic processes and are most useful in the later stages. The tissue reaction is qualitatively the same in all stages, however, and there are grounds for supposing that the syphilitic infiltrate tends to bury the parasites, making them inaccessible to anti-syphilitic remedies, so that there is a use for iodine preparations in all stages. The favourite preparation is potassium iodide, in doses of 15 to 30 grains thrice daily. It may cause gastro-intestinal disturbance, even when given very dilute in water, and is then better tolerated if made up in a cent. per cent. solution and the dose dropped into milk. The depressing effect of potassium iodide is overcome by giving it with *nux vomica*. Many proprietary preparations are advertised as superior to potassium iodide, but they should be reserved for cases where the older preparation cannot be tolerated. Sodium iodide is probably the best preparation for intravenous injection. In this case, after testing the patient's tolerance by giving some potassium iodide by mouth, a dose of 150 grains of sodium iodide dissolved in 100 c.c. or more of sterile distilled water is given intravenously every 24 to 48 hours up to a total of 20 to 30 injections per course.

Use of the above Remedies in the Management of Acquired Syphilis

The main principles to be observed in the treatment of syphilis are—(1) to begin as early as possible, before the micro-organism has become buried in the sclerosed primary sore or entrenched in comparatively inaccessible regions, such as the central nervous system; (2) to continue as long as experience shows that there is a possibility of the patient relapsing if treatment ceases; (3) to exploit the patient's natural resistance, by maintaining his general health in the highest possible condition.

Since the decision as to cure has to be postponed for some years after suspension of treatment, and relapse cases are particularly difficult to cure, it is better to treat all cases as if they were of the resistant type. It is a great mistake to stop treatment as soon as the serum reactions become negative, or to continue then with only a feeble form of treatment, such as mercury by mouth.

For early syphilis, schemes of treatment of two main types may be considered, namely, those in which the injections are given over a period of a year or longer, and those—reintroduced comparatively recently—in which

it has been compressed to periods ranging from a single day to about twenty weeks. At once it should be said that the compressed, or intensive, methods and their application should be considered only in circumstances which make it impracticable or undesirable for the patient to attend for the long period considered necessary in routine work. This is because the more intensive treatments are attended by more danger, and require greater care for their administration. It seems possible, however, that, as indicated at the beginning of this section, the use of penicillin may make it unnecessary to approach the toxic borderline in schemes of treatment designed to eradicate the disease within a comparatively few weeks. Indeed, it is not unreasonable to be even more optimistic than this and to envisage the eradication of syphilis with perfect safety within a comparatively few days. At present, however, the only course is to proceed on the assumption that penicillin is not available to any but the favoured few.

For routine work employing the long schemes, the choice lies between two main lines, the intermittent concurrent, which is the most commonly employed in this country and in Europe, and the alternating continuous, which has hitherto been the most popular in the U.S.A. The advocates of the latter system have written many articles to prove that this is better than what they call "intermittent treatment," but the intermittent treatment with which they have compared the results of their alternating continuous scheme is not that which is practised in the best centres in this country. The respective merits of the two schemes worked at their best could be discussed at far greater length than is possible here, and I can record only my view, based on a long experience in this branch of medicine and a careful study of all the evidence, that our intermittent concurrent treatment results in fewer relapses, especially clinical ones, and less disease of the central nervous system. Consequently only the intermittent concurrent system will be described here.

The scheme recommended is based on the recommendations of the Committee of Experts on Syphilis and Cognate Subjects under the Health Organisation of the League of Nations, after an analysis of over 13,000 records of primary and secondary syphilis which had been treated in five countries; it differs from that of the League's Committee chiefly in the lower dosage of neoarsphenamine.

For adult males and non-pregnant females, starting with a dose of 0.45 g. neoarsphenamine or equivalent compound, the course is continued with nine doses of 0.6 g., the injections being given once weekly. Concurrently with the arsphenamine preparation, ten weekly injections of an insoluble compound of bismuth, each containing from 0.20 to 0.24 g. bismuth metal (say 0.25 to 0.30 g. bismuth oxychloride) are administered; or twice this number of injections of a liposoluble compound each containing 0.10 to 0.12 g. bismuth metal, these being given twice weekly. At the end of the first course, the blood is tested and if negative, three more such courses are administered at intervals of four to six weeks. If the blood is not negative at the end of the first course, the treatment is continued for three courses after that which has ended with negative reactions.

In pregnancy the prime aim is to keep the spirochete from entering the circulation of the foetus, and this is best ensured by starting the treatment before the end of the fourth month. The treatment should be continued practically to the end of the pregnancy, but since recent investigations suggest

rather strongly that pregnant women are more prone than others to develop arsenical encephalopathy, especially towards the end, it may well be advisable to keep the individual dose of the neoarsphenamine, or equivalent remedy, to a maximum of 0.45 g. Experimental and other evidence suggests that arsenic does not enter the foetal circulation until at any rate the end of the pregnancy, but radiograms of the bone-ends of new-born infants show that bismuth passes the placenta at any time. This being so, one must rely mainly on bismuth to keep any *S. pallida* that have invaded the foetus in check. Throughout, it is of course necessary to keep a close watch on the urine for evidence of damage to liver or/and kidneys.

In the above schemes the arsenical remedies recommended are neoarsphenamine and arsphenamine diglucoside for the intravenous route, and sulpharsphenamine for the deep subcutaneous or intramuscular. The question arises, what should be the dosage of oxophenarsine if a preparation of this class is substituted? The question is not easy, because a comparative estimate of the respective therapeutic effects of oxophenarsine and the arsphenamine compounds has not been made on a sufficiently large scale, but, on present evidence, I should not feel justified in giving less than 0.14 g. oxophenarsine (in two or more injections) in place of 0.6 g. neoarsphenamine or similar remedy.

Observation of the blood throughout the above treatment has been mentioned; on the question when the spinal fluid should be examined opinions differ. Personally, I think that if the blood reactions have remained negative from the first, or have been finally reversed by the end of the second course, it is sufficient to test it on completion of the scheme of treatment and at the end of the two years' period of observation which should follow completion of the treatment. If the blood reactions persist beyond the end of the second course, or if a relapse occurs, it is always advisable to test the fluid earlier. Many syphilologists recommend earlier and more frequent tests of the spinal fluid, but after all, lumbar puncture can be followed by severe headache, which can make the patient quite determined not to repeat the experience, and under the scheme outlined above I have seen no cause for regret in following the advice just given.

After completion of the treatment, the blood should be examined every three months for a year and every six months in a second year.

For the scheme of treatment of early syphilis with neoarsphenamine, arsphenamine diglucoside, or sulpharsphenamine in conjunction with bismuth on the lines set out above, satisfactory results approximating 100 per cent. have been claimed by some workers in this country. Unfortunately many patients attending the public clinics do not persevere to the end of the scheme, and many wild statements have been made to the effect that they spread the disease. This is by no means invariably the case. There is good evidence that even a few injections cure many cases of syphilis, and a high percentage are cured by as little as two courses. On this point detailed evidence would occupy too much space, but as something more must be said about the intensive short schemes of treatment already mentioned, and by way also of showing that they are neither new nor dependent for safety on the use of oxophenarsine, it may be worth while to recall that in 1914, W. Gennerich (Kiel) reported 95 per cent. of satisfactory results in 162 cases of primary and secondary syphilis which had been treated for relatively short periods and had been particularly well observed for a minimum period of one year

afterwards. The 92 primary cases in this series had received a maximum each of 11 injections of old salvarsan, totalling 4.4 g. (equivalent in arsenic to 5.8 g. neoarsphenamine) and 15 injections of calomel, totalling $7\frac{1}{2}$ to 12 grains, in about two months. The 70 secondary cases had received each, a maximum of 6 g. salvarsan (equivalent in arsenic to 9 g. neoarsphenamine) in conjunction with 12 to 18 grains of calomel in a period of about four months.

Intensive Schemes of Treatment of Short Duration

Very little space can be given to the intensive schemes re-introduced a few years ago by Chargin, Leifer and Hyman, with the administration of 4 g. neoarsphenamine by intravenous drip-feed in five days, and since then modified by giving multiple injections over varying short periods of time. The popularity of the method has received a great impetus because of the perennial difficulty of getting patients to complete the older long schedules of treatment, a difficulty which has been increased by the circumstances of the war. The modifications have aimed to eliminate the high mortality resulting from the five-day treatment compatibly with securing a high cure-rate. Of the many multiple injection schemes, only the following can be mentioned :

(a) The U.S. Army routine scheme, now superseded by penicillin, lasted 26 weeks, and provided for the injection of oxophenarsine ("As." below) in doses of 0.05 to 0.07 g. and bismuth salicylate ("Bi." below) in doses of 0.2 g. on the following plan: 10 injections of As. at the rate of 2 a week concurrently with 5 of Bi. at the rate of 1 a week; 10 of As. at 2 a week; 6 Bi. at 1 a week; 10 As. at 2 a week; and 10 As. concurrently with 5 Bi., as at the outset. (b) The twelve-week scheme, proposed by Eagle as a result of very extensive experiments on animals, consists of 36 injections of As. at the rate of 3 a week, concurrently with 12 of the Bi. at the rate of 1 a week.

The foregoing schemes can be practised on out-patients. Modifications bridging the gap between them and the original five-day method are the ten- and the twenty-day courses, which require hospitalisation and are attended by a mortality inversely proportional to their length.

Another scheme proposed for merchant seamen by an international committee of medical experts which sat at the Ministry of Health in November 1942 provides for a first course of 12 injections of 0.45 g. neoarsphenamine at the rate of two a week, concurrently with 12 of bismuth, to be repeated at the first opportunity after three months.

In later syphilis, i.e. after the third or fourth year, the line of treatment depends very much on the involvement of viscera and/or nervous system, the treatment of which is discussed elsewhere in this work. It is very important in these later cases to examine carefully the cardio-vascular and nervous systems. If the cerebro-spinal fluid is positive, there is little hope of restoring it to normal by ordinary anti-syphilitic treatment. In such cases tryparsamide is probably the best remedy to employ as soon as it is seen that trivalent arsenical preparations are not influencing the state of the spinal fluid. It is given intravenously in weekly doses, commencing with 2 g. for an adult and increasing at once to 3 g., dissolved in 10 c.c. distilled water, in courses of about 10 injections, with intervals of about 6 weeks between courses. The concurrent use of bismuth is advantageous in these cases. Assuming that, as

is usual, no sign of optic nerve disturbance appears, patients commonly tolerate very large total amounts of tryparsamide—as much as 10 or more courses. The cerebro-spinal fluid should be examined periodically, and the tryparsamide treatment is continued in regular courses, with intervals, so long as improvement is steady. If no improvement in the state of the fluid is apparent by about the end of the third course, one considers the institution of pyretotherapy, of which probably the most effective form (apart from the use of physical apparatus for production of fever) is malarial inoculation, and usually about ten paroxysms of fever are allowed before interference by means of quinine or some similar remedy.

Both malaria and the use of physical apparatus may be impracticable, as the patient usually feels well and also may be a busy man unable to spare the time for, or perhaps explain to his family the necessity of, entering a nursing home or hospital for a course of malarial paroxysms, or of fever produced by physical agents. For this reason it is usually more practicable to try at first a course of fever induced by simpler means, such as the intravenous injection of a vaccine. The most popular for this purpose is anti-typhoid vaccine, of which the dose may begin at 200 millions and be increased with successive injections, given every other day, by about 80 per cent. The aim is to provoke a rise of temperature to about 104° F., which is reached a few hours after the injection. The disadvantage of vaccine injections given in this way is that the patient quickly becomes tolerant, and even large increases of the dosage produce very disappointing results in respect of temperature rise, so that there is much to be said for the method of Nelson whenever it is practicable. In this the patient receives two doses each day, each smaller than would be necessary by the single-dose method, the second being given 2 or 3 hours after the first, when the fever produced by this is at its height; the effect is to flick up the temperature to a much higher level. The scheme shown in Nelson's paper used T.A.B. vaccine. After preliminary single doses of 70 and 140 millions on the first and second days, resulting respectively in temperatures of 103.6° F. and 103° F., on each of the next 11 days two doses were given. The first of these ranged from 25 to 75 millions, and the second was sometimes the same as the first, and sometimes as much as 80 per cent. higher. If the second dose does not produce a sufficient rise, a third given before defervescence may do so. Many workers have now reported well on this method. A disadvantage of both the malarial and the vaccine methods of inducing pyrexia is that once a paroxysm has started, it is more or less out of control. A method which affords better control is the administration of T.A.B. vaccine by the intravenous-drip system, as recommended by Cronin in this country for the treatment of gonorrhoea and by Lawrence in the U.S.A. for the treatment of syphilis. Cronin's method is to administer 0.2 c.c. of the standard T.A.B. vaccine, and 2 hours later commence giving by the intravenous route T.A.B. vaccine, in a concentration of 4 c.c. in 600 c.c. glucose-saline, at the rate of a drop a second. Thereafter, the temperature response is regulated by the speed of the drip, which may be maintained for 4 or more hours. Another method is to inject intramuscularly a solution of sulphur in oil, such as sulfosin, beginning with 1 c.c., and increasing to 10 c.c., according to the temperature provoked. After the fever treatment it is best to continue with the tryparsamide and bismuth, or with some form of ordinary anti-syphilitic treatment.

For cases of tertiary syphilis affecting the external and supporting structures and for latent ones, when the cerebro-spinal fluid is negative, the first course can usefully be on the same lines as shown above for early cases, while in later ones it may be preferable to rely more on bismuth, giving this entirely, or interspersing a few doses of an arsphenamine preparation. It is well also to administer considerably more iodine to later cases. In these later cases it is often very difficult or even impossible to convert the serum reactions to negative, and many syphilologists will not treat them beyond the stage when they show no clinical signs, maintaining that it is hopeless to convert the reactions, that the treatment only gets on the patient's nerves, and so forth. I am sure that this view is mistaken. Patients with latent syphilis who have not complained of any particular feeling of ill-health commonly remark after the first or second course of treatment that they now feel better than they have done for years; it is as if an insidious depressor of health had been removed. Moreover, it is not true that treatment of these cases has no effect on the serum reactions. If a serum test is employed which measures the strength of reaction in units, the effect of treatment is obvious. Thus, in a case tested by the Sigma method, before treatment the reaction may be, say, 36 units; at the end of the first course in such a case it is often 18 or 20 units; at the end of the second course, 8 or 10; and so it gradually becomes reduced to 2 or 3, a number which is still regarded as positive. At this it is apt to remain, but here a change to mercury by mouth for some months often reduces the strength of the reactions quite remarkably. I usually treat steadily until the figure indicating the strength of serum reaction has not been reduced for two or three courses, and then advise continuation treatment at the rate of about three courses in 2 years.

CONGENITAL SYPHILIS

An infected mother can transmit syphilis to her offspring long after she has ceased to be sexually contagious. Syphilis transmitted to the foetus during the early months or years of the mother's disease is usually fatal, and a miscarriage results. In the classical case, in successive pregnancies miscarriages of viable foetus are succeeded by still-births at term, by infants born alive but dying shortly afterwards, by infants which survive though syphilitic, and eventually by healthy ones. This history of gradual attenuation of the infection is, however, not invariable; in some families a healthy infant may be sandwiched between diseased ones, and in the case of twins one only may be syphilitic. It is generally believed that transmission almost always occurs through infection of the mother, though a few workers consider that the ovum can be infected directly. The foetus is commonly infected in the second half of pregnancy.

Symptoms.—A syphilitic infant born alive may show an eruption of bullæ or pustules resting on dark-red bases. The secretion contains *S. pallida* in large numbers. A commoner event is the maculo-roseolar eruption, coming on about 3 weeks or a month after birth. It selects chiefly the napkin area, the neighbourhood of the nose and mouth, and the palms and soles, but the whole trunk and limbs may be affected. The macules often run together into large patches which may be annular, as in the recurrent form

of acquired syphilis. In moist areas, and where the rash is exposed to friction, the affected area becomes red and glazed, or crusted. Condylomata and moist papules occur especially in the ano-genital area, and ulcerative fissures or rhagades may form at the angles of the mouth. These rhagades often leave radiating scars which remain as stigmata of the disease. The nails may become opaque and irregular, or there is infiltration and oozing of serum around the nail, which is loosened and shed. The hair is often shed extensively; on the other hand, syphilitic infants may grow an abundant crop of hair, which has been called the "syphilitic mop," though it occurs in other diseases. Mucous patches in the nose, mouth, throat and larynx cause the well-known "snuffles" and the hoarse, raucous cry of the syphilitic infant. Suppurative otitis media is often an early manifestation, and leads to hopeless deafness.

Tertiary lesions may appear very early, or not until the ages of 7, 14, 21, or even later. Thus diffuse *interstitial orchitis* may occur during the first 6 months. Skin gummata may appear in the first year or two as small infiltrates which break in the centre to discharge their mucoid contents. Tertiary lesions of the mouth and throat may appear at any time after the first year, and result in perforation of the palate and great deformity of the soft palate and faucial pillars. Destruction of the nasal support results in saddle-nose, and from the age of about 11 there is a liability to sudden deafness from gummatous changes of the internal ear. The affection usually starts in one ear, but quickly follows in the other, and the child becomes permanently deaf. *Choroiditis* and *iritis* may appear as early as the age of 5 months, and, unless properly treated, lead to blindness, or considerable impairment of sight. *Interstitial keratitis* may begin at any age from 6 to 30 or even later. Usually it starts in one eye, and the other follows suit in a few months, often in spite of treatment. The cornea of the affected eye gradually becomes opaque from the margin inwards, and this is followed by vascularisation, causing a pink patch (*salmon patch*); the cornea may gradually weaken and bulge before the intra-ocular pressure, or it may ulcerate. Gradually, after many months, the cornea may clear more or less completely, but the patient is often left with permanently damaged sight owing to concomitant iritis and choroiditis. The permanent teeth may show signs of congenital syphilis in the form of notching of certain teeth, which are narrowed at their cutting bases (*Hutchinson's teeth*). The two upper central incisors are much the most usually affected, but all the incisors may be notched. These characteristics are usually lost after the age of 20. The first molars are often dome-shaped (*Moon's teeth*).

The long bones may be affected in various ways. Syphilitic epiphysitis (Wegner's "*osteo-chondritis syphilitica*") is a very constant effect of congenital syphilis, being detectable at birth by radiographic examination, which shows broadening and irregularity of the epiphysodiaphyseal zone. This radiographic examination is very valuable for diagnosis during the first 6 months; afterwards the appearances may not be so characteristic. Epiphysitis may cause signs simulating paralysis (*syphilitic pseudo-paralysis*) owing to the rapid loss of movement which occurs. Movement of the limb causes severe pain, which explains the apparent paralysis. The epiphysis is swollen, and occasionally definite separation occurs. Arthritis may be associated with epiphysitis, and the joint may suppurate. Between 5 and 18

years of age chronic synovitis may appear, affecting chiefly the knees, with swelling of joints (*Clutton's joints*), but with slight pain or interference with movement.

Dactylitis occurring in the second year causes fusiform swelling of the proximal phalanges of two or more fingers, or, more rarely, toes. At a later period in childhood, between the ages of 8 and 14, chronic periostitis of long bones is apt to cause characteristic deformities, best shown in the tibiae, which becomes shaped like sabre-scabbards.

The visceral and nervous affections of congenital syphilis are dealt with in other sections, and here it must suffice to say that in infants and young children anæmia and marasmus, as also delayed development and proneness to death from intercurrent affections, are common consequences of congenital syphilis.

Diagnosis.—The serum reactions at birth and for some weeks afterwards should be interpreted with caution. It has been shown by Fildes, Whitridge Williams, Cruickshank, Dunham and others that an important proportion of those born with positive blood become negative later, and vice versa. In a non-syphilitic infant any positive reaction dies out rather quickly, and if there is reason to hope that, through treatment of the mother or the age of the infection, the infant has escaped, before accepting a positive reaction as diagnostic the test should be repeated quantitatively at weekly intervals; maintenance or strengthening of the reaction over some weeks would justify a diagnosis, and vice versa.

Syphilitic pemphigus occurs on the palms, is earlier than ordinary *pemphigus neonatorum*, and *S. pallida* can be found in the secretion. Ordinary *erythmata* are brighter red, and associated with friction and moisture such as from wet napkins, while the syphilide is not necessarily accounted for by friction, or by moisture, and is associated with such signs as "snuffles" and chronic laryngitis.

Syphilitic epiphysitis is distinguished from *true paralysis* by the pain on movement and contraction of the muscles when the skin is irritated. It occurs earlier than *scurvy* or *rickets*, appearing about the third week, and is associated with the skin and mucous-membrane lesions of syphilis. It is well to remember that syphilis has been found to be responsible for many of the nutritional and mental disorders of childhood, and that it is advisable to investigate every obscure case with syphilis in view.

PROPHYLACTIC.—The prevention of transmission to offspring is primarily a matter of preventing infection of mothers. A man who has contracted syphilis should be advised to wait for at least five years before marrying; by that time the risk of transmission by sexual intercourse has usually gone, whatever the treatment. The period can be shortened by treatment, but this must be prolonged and thorough. A syphilitic woman is liable to convey the disease to her offspring throughout the child-bearing period, especially in the first five years of the infection, but efficient treatment commenced in the first half of pregnancy will usually protect the foetus; if treatment is started later and the mother's infection is recent, it is usually safest to regard it as remedial and to continue treating the infant after birth.

CURATIVE.—The following rules may help in deciding whether or not an infant born of a syphilitic mother should be treated, and the lines of treatment in the event of this being necessary:

As already mentioned, it is unsafe to rely on a positive serum reaction for a decision to treat, or on a negative one for a decision to withhold treatment.

(1) *S. pallida* can usually be prevented from entering the foetus by commencing the treatment of the mother in the first half of pregnancy.

(2) The older the infection of the mother, and the earlier she is treated in her pregnancy, the greater the justification for a "wait and see" policy in regard to treatment of the offspring after birth.

(3) If the mother's syphilis has been treated indifferently and is of less than five years' duration, and if her treatment in this pregnancy was started later than the 4th month, it is safest to treat the offspring.

(4) Either the infant is infected or it is not infected. Precautionary treatment, so called, is given on the assumption that it may be infected and should be as complete as if infection had been proved completely.

(5) (a) If it is decided to give arsphenamine and bismuth, the scheme of treatment may be on the lines set out in the League of Nations Schedule, giving intramuscularly, 0.02 g. sulpharsphenamine and 0.004 g. bismuth metal per kg. infant (say 0.08 g. sulpharsphenamine and 0.20 c.c. of a 10 per cent. suspension of the oxychloride, or 0.8 c.c. of a similar suspension of the iodo-bismuthate of quinine for an infant weighing 9 lb.). (b) In place of sulpharsphenamine it may be more convenient to give acetarsol (p. 226) by mouth. In this case the following, in conjunction with heavy metal, would probably suit most cases. The drug is given in water half an hour before the first feed, and the dosage is based on the infant's weight as follows:

1st week, 0.005 g. per kg. per diem.

2nd " 0.010 " "

3rd " 0.015 " "

4th to 10th week, 0.02 g. per kg. per diem.

4 weeks' rest.

The course of acetarsol and bismuth should be repeated three times after the blood has become negative. (c) Instead of bismuth treatment shown in (a) and (b), inunctions with mercury ointment (15 to 60 grains of the B.P. preparation, according to age) can be given daily throughout each course except in the fifth week, or yellow mercurous iodide $\frac{1}{2}$ grain dropped into the milk three times a day.

In older children and adults with congenital syphilis the treatment is on similar lines to those employed in corresponding stages of acquired syphilis, but there is here probably more reason to supplement the injection treatment by pyrogenetic measures.

L. W. HARRISON.

YAWS

Synonyms.—Frambœsia: Frambœsia tropica; Pian; also many vernacular names such as Parangi (Ceylon), Bubas (Brazil), Coco (Fiji), etc.

Definition.—A contagious, inoculable, tropical disease caused by *Treponema pertenue*. The primary lesion is of non-venereal origin and is followed by the secondary stage consisting of an eruption of typically granulo-

matous papules. The tertiary stage, occurring a few or many years later, is characterised by destructive lesions.

Ætiology.—Yaws is essentially a disease of indigenous populations of tropical countries. Europeans are rarely affected. It is prevalent in the West and East Indies, Ceylon, the Philippines, Oceania and New Guinea, and parts of tropical Africa and South America. Infection usually occurs in childhood, although a few adults escaping infection then may contract it later. The disease is not transmitted congenitally, and infection is generally regarded as occurring only once in a lifetime. Both sexes are attacked. The cause is the *T. pertenue*, which is morphologically indistinguishable from the spirochæte of syphilis; on animal inoculation, however, constantly different reactions have been observed. The similarity of yaws and syphilis is greatest in the tertiary stage. Bejel, the non-venereal syphilis of the Bedouin Arabs, has certain epidemiological and clinical similarities to yaws. *T. pertenue* enters the skin through minor abrasions, most commonly on the limbs and especially the legs.

Pathology.—The primary and secondary lesions are characterised by interpapillary down-growths of epidermis into the corium. There is also cedema and infiltration with polymorphonuclear leucocytosis and plasma cells both in the proliferated epidermis and in the corium. Spirochætes are more numerous where the cellular infiltration of the epidermis is most pronounced, but they are also present in the adjacent corium. The tertiary lesions are characterised by necrosis and ulceration with granulation tissue and dense fibrous tissue. Giant cells are frequently present, but spirochætes are not numerous. Though peri-vascular cellular infiltration and vascular endothelial proliferation are usually said not to occur in yaws lesions, there are no generally reliable histological criteria for the differentiation of yaws and syphilitic skin lesions in man.

Symptoms.—The incubation period in man is four weeks or longer (in monkeys three weeks), and may be accompanied by mild general symptoms.

The primary lesion, which is not always demonstrable, resembles the typical secondary lesions but is often larger. It is usually single and extra-genital, and may heal before the secondary eruption appears or outlast it. The adjacent lymphatic glands may be enlarged.

The *secondary stage*, which may appear within three weeks of the primary lesion, may be heralded by irregular intermittent fever, headache, bone and joint pains, often worse at night, and a characteristic more or less generalised papular eruption. This commences as small, yellowish papules, which increase in size or coalesce to form larger lesions. The stratum corneum is shed, exposing a granular surface of minute pinkish elevations, separated by a whitish groundwork. Serum containing treponemata exudes and dries, forming a yellowish crust, which later may become discoloured and polished, especially in the case of less active lesions. Pus is not usually present. Healing occurs sooner or later, often leaving but little scarring, although hyperpigmentation, which later disappears, may be seen. The lesions may itch, and, although not very painful, are sensitive to minor irritation, such as flies. The distribution is general, but the trunk is often relatively spared. The body orifices and the soft skin of flexures are particularly involved. Successive crops may appear for from two or three years. Other types of skin lesion, pathologically related to those just described, are often seen, but usually typical secondary

lesions are also present. General enlargement of the lymphatic glands is often found. The eruption of a yaw on the sole, clavus or crab yaws, is particularly painful, and may occur many years after the earlier lesions have healed. Yaws papules may also occur on the buccal mucous membrane. Bone lesions are frequent during this stage, and are characterised by swellings. Periosteal deposits and rarefied foci in these deposits and in the cortex are seen radiographically. Sabre-tibia may develop, but destructive bone lesions do not occur. Multiple dactylitis is frequent. Ganglia and synovitis with free fluid are seen. Goundou belongs to this stage. All secondary lesions heal spontaneously, although bony deformities remain. The general health is not usually seriously affected.

The *tertiary stage* may be reached within a year of the healing of secondary lesions, or after a quiescent period of many years. Lesions at this stage are characterised by tissue destruction and ulceration. In the skin superficial ulceration or deep gummatous-like processes may occur, which on healing leave hyperpigmented atrophic scars and occasionally contractures. In the bones, swellings with ulceration associated with bony necrosis ("gummata"), spontaneous fractures, deformities of the digits, periostitis, nodes, synovitis and arthritis are seen. Destructive processes in the mouth and nose may lead to palatal perforation and to gangosa. Epidermal thickening, erosions, fissures and coarse desquamation occur on the palms and soles, some of which may return to normal, but others result in atrophic changes, pigmentation and contractures of the fingers. Juxta-articular nodes, chronic bursitis and patchy depigmentation of the skin are also met with.

Complications and Sequelæ.—In severe tertiary cases with many lesions, cachexia may result. Intercurrent diseases may be present. In Fiji and Haiti aneurysm and lesions of the central nervous system have been attributed to yaws, but the evidence is not convincing.

Diagnosis.—In localities in which yaws is prevalent there is usually no difficulty in diagnosing the early lesions, but congenital and acquired syphilis, bejel and bromide rashes may occasionally call for consideration. *Treponema* can usually be found in serum from early lesions. The differentiation of tertiary lesions from syphilis may be impossible on clinical or pathological evidence, and a history of yaws in the past may be the only guide. Cutaneous leishmaniasis, blastomycosis, leprosy and tuberculosis may lead to confusion. The Wassermann and Kahn reactions are positive in yaws and syphilis after the first few weeks. The absence of mucous patches, visceral, vascular and central nervous system lesions in yaws and its ready response to modern arsenical and bismuth preparations may help to differentiate the two diseases.

Prognosis.—All secondary lesions heal spontaneously in a few months or years, and probably some cases become spontaneously cured and develop a negative Wassermann reaction. Yaws is rarely fatal, most deaths being due to intercurrent disease. Modern therapy is effective. In tertiary lesions more intensive treatment is required to produce healing and here, too, spontaneous cure probably occurs although less readily.

Treatment.—**PROPHYLACTIC.**—Avoidance of direct contact with cases of yaws is the basis of prophylaxis. Ordinary cleanliness, and the covering of cuts, abrasions and ulcers with suitable dressings to prevent contact with infective material and flies are important.

CURATIVE.—Such drugs as neoarsphenamine, which are specific for

syphilis, are also specific for yaws. While two or three intravenous injections may completely clear up the primary or secondary yaws lesions, it has to be remembered that clinical cure is not synonymous with eradication of the infection. Not infrequently the Wassermann reaction persists. A series of neoarsphenamine injections (0.6 g., adult) should be given, and when possible they should be combined with intramuscular injections of bismuth, as in syphilis. Owing to cost and for other reasons, this is frequently impossible in natives. Under these circumstances intramuscular injections of bismuth may have to be relied on. Sodium-potassium-bismuth-tartrate (0.15 to 0.3 g.), bismuth oxide (0.2 g.), bismuth salicylate or metallic bismuth (0.1 to 0.2 g.), suspended in oil, may be used. Intramuscular injections should be administered into the buttocks at least once weekly for six weeks. Toxic features, including stomatitis, albuminuria, diarrhoea and skin rashes, may complicate this treatment. Stovarsol (acetarsone) or carbarsone, may also be given by the mouth with satisfactory results. The response is much slower with arsenicals and bismuth preparations than with neoarsphenamine. In tertiary yaws, potassium iodide is of value.

Local treatment is necessary if there are extensive ulcers and lesions involving the soles of the feet. Deformities associated with periostitis and contractures may need plastic surgery.

GOUNDOU

Synonyms.—Anakhre ; Gros Nez ; Dog Nose.

Definition.—Symmetrical bony tumours of the sides of the nose commencing during the secondary stage of yaws.

Ætiology.—This condition is found wherever yaws is prevalent, but has been reported most often from tropical Africa, especially in the west. It is seen in children and adults.

Pathology.—There is thickening of the periosteum with production of spongy tissue in which are fibrosis and perivascular plasma cell infiltration. The bony tissue is usually bounded by a thin layer of cortical bone. This hypertrophic osteitis involves the nasal process of the superior maxilla. In marked cases the tumour may encroach upon the nasal passages, orbit, or palate.

Symptoms.—Osteocopic pain, headache, and a thin blood-stained purulent nasal discharge may occur in the early stages, but later these subside. The paranasal swelling on one or both sides increases outwards, and may become large enough to obstruct vision. Facial deformity may be the only symptom, but nasal obstruction may also result. The over-lying skin is not implicated. Sometimes similar tumours elsewhere on the superior maxilla, or on the inferior maxilla, and other yaws bone lesions may also be present.

Diagnosis.—In yaws communities the paranasal swellings are characteristic, but in isolated cases differentiations may be needed from syphilitic osteitis, leontiasis ossea, and possibly acromegaly.

Prognosis.—Though distressing, the disease rarely causes death. Some reduction in the size of the lesions in early cases may occur spontaneously or after treatment.

Treatment.—Energetic anti-yaws therapy is indicated in early cases, and surgical removal of the bony tumour in advanced ones.

GANGOSA

Synonym.—Destructive Ulcerating Rhino-pharyngitis.

Definition.—An ulcerative process of tertiary yaws resulting in destruction of the palatal and nasal structures.

Ætiology.—This condition is probably to be found wherever yaws is endemic. Its presence in the Pacific Ocean Islands and the East Indies has been stressed. It may commence in older children and adults.

Pathology.—The process begins with ulceration of the palate or in the nose, and is followed by destruction of soft tissues and bone. The histopathology is that of tertiary yaws.

Symptoms.—Pain, purulent discharge and foul odour accompany the ulceration mentioned above. The amount of destruction produced varies from a small perforation of the soft or hard palate, or some falling in of the nose to complete destruction of the palate, nose, nasal contents, and adjacent tissue of the cheeks and orbit so that the roof of the nasal cavities, pharynx and tongue are exposed. Arrest of the process, either spontaneously or following therapy, may occur at any stage. The larynx is probably not affected.

Diagnosis.—In yaws communities this is usually easy, but differentiation from American dermal leishmaniasis, syphilis and leprosy may be necessary.

Prognosis.—The progress of the destruction and healing is usually slow and often progressive, and although the response to adequate treatment is good, tissue losses remain. Death may result from general exhaustion, sepsis, insuflation pneumonia, or other intercurrent disease.

Treatment.—Energetic anti-yaws therapy is indicated, and intercurrent disease may need treatment.

JUXTA-ARTICULAR NODES

Definitions.—Multiple, painless, fibrotic nodules occurring in the vicinity of joints and bony prominences in the later stages of yaws.

Ætiology.—This condition is probably found wherever yaws is prevalent, and has been reported from most tropical countries. It is rare in childhood and is characteristically seen in elderly people often together with chronic pre-patellar bursal enlargement. Similar lesions are occasionally met with in late syphilis and in bejel.

Pathology.—The nodules consist of hard, greyish-white, avascular fibrous tissue, in which may be opaque yellow spots and occasional areas of necrosis. Foci of chronic inflammatory cells are found microscopically; endarteritis is said not to occur but treponemata have been demonstrated in them. The tumours have no capsules, and merge into the neighbouring connective tissue.

Symptoms.—The nodules appear as small round multiple tumours in the subcutaneous tissue about joints and bony prominences, especially the knee, elbow and over the femoral trochanter. Only a few are present at any one situation; they are painless, firm and even cartilaginous in consistency, and only rarely break down and ulcerate. They are usually freely movable under the skin, but later some attachment to the skin at the most prominent point

may occur. Their development is slow, and the nodules may resolve spontaneously or remain stationary. Their usual size is 1 to 2 cm., but some may become much larger.

Diagnosis.—Differentiation from syphilitic, rheumatic and onchocerca nodules may be necessary. Biopsy may be of assistance. In onchocerciasis the tumours are often softer, and embryos may be demonstrated in aspirated fluid; on section they are loculated, and filariæ and embryos are present.

Prognosis.—The nodules may cause some discomfort at points of pressure, but do not endanger life.

Treatment.—If necessary, troublesome nodules may be excised. Intensive anti-yaws therapy may cause resolution in some and regression in others.

LEPTOSPIROSIS

Since the causative organism, *Leptospira icterohæmorrhagica*, was first demonstrated in Japan by Inada and Ido in 1915, spirochætosis icterhæmorrhagica has been recognised in many different countries. The earliest observations indicating that strains of leptospira other than the classical spirochætosis icterohæmorrhagica strain might produce disease in man was made two years later in Japan when *L. hebdomadis* was shown by Ido, Ito and others to cause Japanese seven days' fever or Nanukayami disease. Subsequently several strains differing in antigenic structure were discovered in the Dutch East Indies and Malaya. In Europe swamp fever was recognised as a leptospirosis caused by *L. grippo-typhosus*, and in 1932 *L. canicola*, which commonly affects dogs, was shown to produce leptospirosis in man. More recently in Australia several new strains have been isolated. Schüffner classified the leptospiras pathogenic to man on the basis of different antigenic structure as revealed by serological reactions and animal inoculations, the clinical picture, epidemiological considerations and geographical distribution. Many different strains are recognised, and these are separated into two groups, i.e. those capable of producing jaundice and those which fail to do so, but it should be remembered that even in classical spirochætosis icterohæmorrhagica only 50 per cent. of patients develop jaundice. The clinical picture in leptospirosis caused by any of these strains include conjunctival congestion, fever, prostration, severe headache and generalised muscular pains; meningeal symptoms and rashes may also develop. A neutrophil leucocytosis is characteristic. The outstanding difference is in prognosis, for while many cases of classical spirochætosis icterohæmorrhagica die, patients infected with other strains almost invariably recover. Early blood culture, inoculation of guinea-pigs with blood or urine, serum agglutination reactions and other serological tests are essential to establish the diagnosis of leptospirosis and determine the strain of leptospira implicated.

I. LEPTOSPIROSIS ASSOCIATED WITH JAUNDICE

Four strains pathogenic to man are included in this group:

(1) The classical Weil strain, *L. icterohæmorrhagica*, is cosmopolitan in distribution and lethal to guinea-pigs. The natural reservoir is *Rattus decumanus*, and it is known that in many different countries rats of this

species pass *L. icterohæmorrhagica* in large numbers in the urine; these organisms infect man through skin abrasions or via the nasal mucous membranes during submersion in contaminated water. Only rarely the disease is acquired from infected dogs and cats.

(2) Akiyami A strain is similar to *L. autumnalis* of Japan and the Rachmat strain of the Dutch East Indies. The natural host is *Apodemus speciosus* in Japan where it has an autumnal prevalence.

(3) The Salinem strain, or *L. pyrogenes*, of the Dutch East Indies is probably identical with the Zanoni strain, which is one of the two leptospiræ responsible for leptospirosis amongst the cane-cutters of Queensland, Australia, in the rainy season. It has been found in a local species of rat—*R. culmorum*. The strain is lethal to guinea-pigs.

(4) The Batavia strain is found only in Java where *R. decumanus* appears to be the reservoir host. It is less pathogenic for guinea-pigs than the other strains described above.

II. LEPTOSPIROSIS WITHOUT JAUNDICE

A number of different strains pathogenic to man are included in this group. These include:

(1) *L. hebomadis* causes seven days' fever in Japan. It is primarily an infection of the field vole, *Microtus montebelli*, and appears in the urine, which contaminates soil or food. It has recently been found in Sumatra in dogs and man.

(2) *L. grippo-typhosus* gives rise to summer epidemics amongst field workers in Europe, but the reservoir host and mode of infection is unknown. The disease runs a benign course. It has also been isolated from patients with leptospirosis in the Andamans (Andaman B strain).

(3) *L. canicola* produces an epizootic in dogs, from which man acquires the disease by contact. The rat is not a reservoir host. In Canicola-fever, though jaundice is absent, the meningitic symptoms often appear more severe than in classical Weil's disease. In inoculated guinea-pigs its virulence is enhanced with passage.

(4) The Pomona strain produces fever lasting three to eight days, and has been isolated from agricultural workers in Queensland. It occurs after rain.

(5) The Ballieo strain causes leptospirosis in Queensland on the cane plantations after rain. It produces a mild fever lasting a week. It is lethal to guinea-pigs and has been found in local rats.

N. HAMILTON FAIRLEY.

SPIROCHÆTOSIS ICTEROHÆMORRHAGICA

Synonyms.—Spirochætal Jaundice; Weil's Disease.

Definition.—An acute febrile disease with a world-wide distribution, caused by *Leptospira icterohæmorrhagica*, and generally occurring in people with an occupational relationship to rats. In its typical severe form it is characterised by fever, profound prostration, headache, generalised pains

and acute muscular tenderness, conjunctival hyperæmia, leucocytosis, albuminuria, jaundice, and a tendency to hæmorrhage. Subclinical infections may occur, and jaundice is absent in about 50 per cent. of cases.

Ætiology.—In 1886, Weil first directed attention to this disease, which is now associated with his name. In Japan it was well known amongst miners and labourers in the rice fields, and in 1914 Inada and Ido infected guinea-pigs with blood from human cases and demonstrated *L. icterohæmorrhagicæ* in the tissues. Later, rats (*Rattus decumanus*) were found to be the reservoir host; the leptospiras, which were localised in the kidney, escaped in the urine and often contaminated water, fungal slime and soil. In man infection generally occurs in people who work in rat-infested places, and follow occupations in which minor injuries and abrasions of the skin are common; this accounts for its incidence in sewer labourers, bargemen, canal and dock workers, fish and tripe cleaners, coal miners and farm labourers. In Great Britain the disease is recognised as an occupational one, for which compensation may be claimed under the Workmen's Compensation Act. In trench warfare troops may become infected. The disease may also be acquired via the nasal passages from infected water when bathing or during immersion accidents, which mode of infection is particularly common in Holland.

Pathology.—(1) MORBID ANATOMY.—In fatal cases there is an acute hepatitis with jaundice, while parenchymatous degeneration of the tubular epithelium of the kidneys, perhaps associated with hæmorrhages into Bowman's capsules, is characteristic. Large and small hæmorrhages are often scattered throughout the tissues and particularly affect the stomach, intestinal mucosa, and the lungs.

(2) ISOLATION OF THE LEPTOSPIRA.—*L. icterohæmorrhagicæ* may be isolated by blood culture on Fletcher's medium during the first week, or by injecting 5 c.c. of infected whole blood intraperitoneally into the guinea-pig up till the tenth day of the disease. In the cultures there is a time lag of three to five days before leptospiras are found, and of five to eight days before they appear in the viscera or blood of inoculated guinea-pigs. Where meningeal symptoms develop leptospiras may be found in the cerebrospinal fluid, and they are often demonstrable in the urine after the second week.

(3) SEROLOGICAL REACTIONS.—The agglutination reaction, using formalised cultures as advised by Schüffner, yields satisfactory results. Agglutinin appears in low titre about the fifth or sixth day, and rapidly increases during the second and third week of the disease; maximal titres up to 1/4000 have been recorded. Agglutinins persist for many years after an attack, and multiple observations to determine an increase in titre may be necessary in cases in which the titre is low and residual agglutinin may have persisted from a previous infection. The adhesion test of Brown and Davis has also proved of definite value.

Symptoms and Course.—The incubation period varies from 6 to 12 days. In moderately severe cases presenting the classical clinical picture three stages are recognised: (1) a febrile stage, with sudden onset; (2) an icteric stage, associated with renal features, and sometimes hæmorrhage; and (3) a convalescent stage, in which febrile relapses are common.

(1) FEBRILE STAGE.—This generally lasts six to eight days. As a rule the onset is sudden, with shivery feelings and definite rigor. Headache, nausea, vomiting, profound asthenia, backache, photophobia, and generalised

muscular pains are characteristic. So severe may the muscular pain and tenderness be that the patient cries out with agony on the slightest movement. Conjunctival injection is common and herpes with hæmorrhage into the vesicles not infrequent. The muscles of the limbs and the abdominal muscles are often exquisitely tender on palpation. There may be some enlargement of liver or spleen but often this is absent even in the icteric stage of the disease. A neutrophil leucocytosis is characteristic; the total count varies between 10,000 to 20,000 leucocytes per c.mm., and the neutrophils equal 80 to 85 per cent.

(2) **ICTERIC STAGE.**—An icteric tinge of the conjunctivæ and lemon yellow tinting of the skin appear from the fourth to the sixth day, but is only found in about 50 per cent. of cases. The jaundice gradually deepens and may become a deep orange in colour. A direct biphasic van den Bergh reaction develops, with well-marked hyperbilirubinæmia; in a recent series one patient whose plasma contained 56 units recovered, and another with a maximum value of 29 units died of cholæmia. With the onset of jaundice the urine becomes dark brown, and contains bile salts and bile pigments. The stools contain excess of fat, which is adequately or excessively split, and are often pale brown or even white in colour, the result of a decrease of stercobilin.

Evidence of renal involvement is not infrequent and the urine, which is decreased in quantity, contains albumin, renal casts, pus cells and perhaps red blood corpuscles. As renal function fails the nitrogenous constituents of the blood increase and the blood urea attains high values. Anuria may ensue. Hiccough, Cheyne-Stokes respiration, subsultus tendinum, delirium and coma are features common to cholæmia and uræmia, which are frequent causes of death. Skin petechiæ or purpuric patches sometimes appear and bleeding gums, hæmoptysis, hæmatemesis, melæna and hæmaturia may complicate the picture.

(3) **CONVALESCENCE.**—This generally commences in the third or fourth week, by which time the renal and hepatic manifestations have subsided, but it is often five or six weeks before the patient is fit to leave hospital. Not infrequently in the third week a relapse of fever occurs, which may last from a few days to three weeks; it is unaccompanied by icterus or other severe symptoms.

Atypical Clinical Types: These are frequent, and may or may not be associated with jaundice. They include:

(a) *Anginal type.*—The patient complains of fever, generalised pains and sore throat, and is usually diagnosed as influenza, tonsillitis or rheumatic fever. Unless jaundice develops or the occupation of the patient suggests the possibility of spirochaetosis ieterohæmorrhagica, laboratory investigations are not made and the true nature of the infection remains unrecognised.

(b) *Abdominal type.*—There is fever, abdominal pain, vomiting and localised or generalised rigidity associated with acute tenderness of the abdominal muscles; the picture may resemble an acute abdominal condition, such as appendicitis, cholecystitis, pancreatitis or peritonitis. A neutrophil leucocytosis is present, and when hæmatemesis occurs, perforated gastric ulcer may be diagnosed.

(c) *Respiratory type*.—There are physical signs of pulmonary consolidation resembling pneumonia, and hæmoptysis may supervene. Jaundice may never develop.

(d) *Meningeal type*.—Not uncommonly leptospiral meningitis, with neck retraction, Kernig's sign, etc. may develop at the onset. Lumbar puncture reveals a clear fluid under increased pressure, containing neutrophil leucocytes, lymphocytes and perhaps monocytes, while leptospiras may be demonstrated by animal inoculation or culture. More rarely, chronic meningitis may supervene months after the acute stage of the disease has subsided, but notwithstanding this the cerebrospinal fluid contains pus cells and leptospiras.

Subclinical infections also occur in which people like sewer workers acquire a symptomless leptospirosis; there is no history of illness yet the blood shows definite agglutination against *L. icterohæmorrhagicæ*.

Diagnosis.—Few diseases are more protean in their clinical manifestations or have remained for such long periods undetected in communities. Spirochætosis icterohæmorrhagica is not generally suspected until the patient develops jaundice and there is known to have been an occupational relationship to rats or a recent water-immersion accident. An appeal to the laboratory under such circumstances will generally enable a delayed diagnosis to be made, either by isolating the leptospira or by serological tests. Apart from jaundice, a history of possible contact with rat-infected material, the extreme prostration, the conjunctival injection and the severity of the muscular pain and tenderness, and the neutrophil leucocytosis, should arouse suspicion.

Prognosis.—Fatal cases are almost invariably jaundiced and die between the ninth or fourteenth day as a rule from cholæmia or uræmia. The mortality rate appears to vary in different outbreaks, but where the diagnosis is reasonably good it is about 15 per cent.

Treatment.—**PROPHYLACTIC.**—This includes the protection of bathing pools, abattoirs, fish shops, etc., from rats, and the immediate treatment and protection of any skin abrasions in people whose occupation brings them in contact with rat-infected material. Prophylactic vaccination is under trial. Nurses should be instructed to disinfect the patient's urine.

CURATIVE.—Penicillin is still under trial, and there is reason to believe it may prove of definite therapeutic value. If anti-leptospiral serum be used it should be given early in large dosage. Fluids and glucose should be administered orally, while intravenous glucose (5 per cent.) is a useful adjunct to therapy in severe cases.

RELAPSING FEVER

Synonyms.—Spirochætosis; Febris Recurrens; Spirillum Fever; Famine Fever.

Definition.—A group of specific infectious fevers due to spirochætes (treponemata) and spread by lice or argasine ticks, characterised by a variable number of febrile relapses.

Ætiology.—Relapsing fever occurs in many parts of the world and is often seen in epidemic form during wars and famines. It is rare in England, but occurs in parts of Europe including Russia; in Turkey,

India, Cochin-China, Algiers, Egypt, Africa and the United States it is not infrequent. All ages and both sexes are liable. The different varieties of the disease are caused by spirochætes demonstrable in the peripheral blood during the febrile paroxysms, and they may be divided into the lice-borne and tick-borne fevers. The varieties transmitted by lice include (1) European relapsing fever due to *Treponema recurrentis* (the old spirillum of Obermeier); (2) Northern African relapsing fever produced by *T. berberum*; (3) Indian or Asiatic relapsing fever caused by *T. carteri*; (4) North American relapsing fever attributed to *T. novyi*. The varieties transmitted by the argasine ticks include (1) Central African tick fever due to *T. duttoni* transmitted by *Ornithodoros moubata*, *O. erraticus* and *O. savignyi*; (2) Palestinian and Syrian tick fever caused by *T. sogdianum* and transmitted by *O. papillipes*; (3) Persian and North-West Indian relapsing fever caused by *T. persicum* and transmitted by *O. papillipes* (*tholozani*) or *O. lahorensis*; (4) Spanish relapsing fever attributed to *T. hispanicum* and transmitted by *O. maroccanus*; (5) Central and South American relapsing fever due to *T. venezuelense* is transmitted by *O. venezuelensis* in Columbia and Venezuela, and by *O. talaje* in Panama; (6) Californian tick fever due to *T. turicata* and transmitted by *O. hermsi*. At present it appears somewhat doubtful whether the creation of the numerous species of spirochætes detailed above is justified on grounds other than those of convenience. Lice become infective about the sixteenth day, and remain so for about one month. Infection is probably conveyed by the feces, or after the louse has been crushed and the spirochætes liberated from the cœlomic fluid; scratching may play an important part in transmission. With ticks the spirochætes are liberated in the coxal fluid, and the anal excrement is also said to be infected; from this source man generally acquires the disease, but it is also possible that it may be transmitted during biting, as spirochætes are demonstrable in the salivary glands of ticks. The ova become infected and new generations of ticks can pass on the disease in hereditary fashion. Larval ticks are as capable of transmitting relapsing fever as adult ticks.

Pathology.—In uncomplicated cases petechial hæmorrhages and occasionally jaundice are found. The spleen is soft and congested and often the site of multiple infarcts, while the liver is enlarged, friable and hyperæmic, and along with the kidneys and heart shows cloudy swelling and fatty degeneration. The long bones contain red marrow. Congestive changes in the cord and brain and iritis have also been described, especially with *T. duttoni*. Microscopically, spirochætes are demonstrable in endothelial cells throughout the body, especially in the liver and spleen, and also in the brain and cerebrospinal fluid. Monkeys are susceptible and, as in the case of rats and mice, are actively immune after recovery. Krantz has applied the Reichenberg reaction or "adhesion test" to relapsing fever spirochætes, specific immune serum causing the spirochætes and blood platelets to adhere together.

Symptoms.—A. THE LICE-BORNE RELAPSING FEVERS.

1. *European form.*—The incubation period varies from 2 to 12 days, and in accidental inoculations it is about five to seven days. During this period slight prodromata may occur. The onset is sudden with a rigor, frontal headache and intense pains in the back and limbs. Anorexia, nausea and vomiting are common, and in children convulsions may occur; the temperature and

pulse rise rapidly, the former often reaching 104° F. on the evening of the first day. The tongue is coated and moist, the spleen is enlarged, and in some epidemics jaundice and a tender enlarged liver may be present. Herpes labialis may develop, and occasionally an erythematous rash appears at onset. Later, rose-coloured spots may involve the skin of the neck, trunk and inner aspect of the thighs. Petechiæ are observed only in severe cases. After the fever has persisted for five to seven days the temperature falls by crisis, accompanied by profuse sweating and possibly diarrhoea and collapse. The patient rapidly improves, but after an apyrexial period a relapse ensues, generally about the fourteenth day, followed by a second crisis about the end of the third week (twenty-first day). This usually terminates the illness, but occasionally a third relapse is noted. Spirochætes are present in the blood until 24 hours before the crisis, when they rapidly disappear, and are not demonstrable except possibly in thick smears during the apyrexial period when a leucopenia replaces the characteristic febrile neutrophile leucocytosis. The blood remains infective between relapses, and if injected into a mouse or white rat spirochætes appear in 24 hours.

2. *Asiatic relapsing fever* closely resembles the European form, but rigors are not so common, collapse is more frequent at the crisis, and relapses more numerous. Carter describes two varieties: (a) a short irregular remittent fever; (b) the so-called bilious remittent or icteric fever. This is a severe form of infection associated with spirochætal hepatitis. There is high fever, intense toxic jaundice, skin petechiæ, splenomegaly, and an enlarged tender liver. The urine contains albumin, bile pigments, bile salts and urobilin. There is hyperbilirubinæmia associated with a direct biphasic Van den Bergh reaction in the plasma. Toxæmic features are marked, and include a dry brown tongue, diarrhoea, abdominal distension, hiccough, stupor, delirium and coma. Death not infrequently results.

3. *North African relapsing fever* is found in Algiers, Tunis and Egypt, and closely resembles the European form. The number of relapses rarely exceeds three, but fatal cases may show jaundice, bilious vomiting, hepatomegaly, splenomegaly with infarctions, and albuminuria, necessitating differentiation from yellow fever.

4. *American relapsing fever* due to *T. novyi* has a low mortality rate and not generally more than one relapse.

B. THE TICK-BORNE RELAPSING FEVERS.

1. *Central African relapsing fever*.—Synonyms.—Tick Fever; Tete Disease; Carapata Fever.

This form is found throughout British and Portuguese East Africa, Nyasaland, Uganda and the Congo Free State.

It differs from the European form in the shorter duration of the initial fever (three days), the irregular incidence, greater number of relapses and the scantiness of spirochætes in the peripheral blood. The incubation period varies from five to ten days, generally being about one week. The tick bites may be accompanied by local inflammatory changes and the prodromata include mental lethargy and sweating. The attack may start gradually with malaise, vomiting and slight temperature which gradually increases, or suddenly with dizziness, headache, and generalised pains, the temperature rapidly reaching 104° F. After the pyrexia is established these

symptoms may persist and, in addition, chilliness, pain over the spleen, bilious vomiting, bronchial catarrh, diarrhoea, enlargement of the spleen and liver, albuminuria and herpes may occur. Generally after three to four days the fever terminates by crisis with profuse sweating. The patient feels weak and tired, but slowly regains his appetite and strength until the next febrile paroxysm, which may occur after an interval of three to eight days. Third and fourth relapses are frequent and as many as ten may occur, weakness and emaciation then being marked. In severe and fulminating cases epistaxis, hæmaturia and jaundice may be met with, also occasionally involvement of the central nervous system, with coma and death due to cerebral embolism caused by tangled masses of spirochætes. Cranial nerve pareses are described, and spirochætes may be present in the cerebro-spinal fluid, which frequently shows increased pressure and lymphocytosis.

2. *Persian and North-West Indian relapsing fever* presents a primary fever of some four days' duration followed by short bouts of pyrexial recurrence; five or more relapses are not uncommon. Some epidemics are very mild others more severe. Often the spleen is not palpable, and icterus is uncommon except in the more severe epidemics.

3. *Spanish relapsing fever* caused by *T. hispanicum* resembles the tick fever of Central Africa. The initial fever lasts about four days, and is associated with splenomegaly and neutrophil leucocytosis. Iritis and facial neuritis are not infrequent complications during relapses, which do not generally exceed four in number.

Complications and Sequelæ.—Bronchial catarrh is not infrequent during the initial fever, and pneumonia and parotitis may also occur. In some epidemics hæmatemesis and hæmaturia have been noted; in others jaundice and hepatomegaly are not infrequent. Rupture of the enlarged spleen has been reported, also ophthalmia, adenitis, neuritis and diarrhoea. In tick-borne relapsing fever (*T. duttoni* and *T. sogdianum*), cranial nerve palsies are not uncommon. The most frequent is unilateral or bilateral facial paralysis, but ptosis of the eyelid, strabismus, deafness, and trigeminal neuralgia are recorded. Ocular lesions include optic atrophy, iritis, iridocyclitis, retinal hæmorrhage, and opacities in the vitreous. Meningismus associated with pathological changes in the cerebrospinal fluid (lymphocytosis, etc.) is quite common.

Diagnosis.—Relapsing fever has to be distinguished from influenza, typhus, malaria and trypanosomiasis, and, if there is jaundice, from yellow fever and Weil's disease. This is done by finding the specific parasite in the blood.

Prognosis.—The prognosis varies. With the European types the mortality rate is only 3 to 5 per cent., but with the Asiatic type it is much higher. Jaundice is an unfavourable development. African tick fever is not infrequently fatal, especially in the aged and debilitated, and Central American tick fevers resemble the Central African variety.

Treatment.—**PROPHYLACTIC.**—Avoidance of contact with lice and ticks is necessary if infection is to be prevented. Delousing of troops in war-time is important. With *O. moubata* the avoidance of native dung huts, especially at night-time, and of old camping sites, is essential. With *O. papillipes* in Syria and Palestine infection is mainly acquired when visiting caves; these should be avoided.

CURATIVE.—Arsphenamine (0.3 to 0.6 g.) and neoarsphenamine (0.6 to 0.9 g.) are specifics in all types of louse-borne relapsing fever; generally not more than two injections are needed for cure. These should be given during the pyrexial period and preferably when spirochætes are demonstrable in the blood smears. In tick-borne relapsing fever these arsenicals are of doubtful value, and with *T. duttoni* in Central Africa and *T. sogdianum* in Palestine and Syria they do not materially influence the course of the disease, or the relapse rate. Claims have been made that Solgonal B. is of value in those cases in which the central nervous system is affected. In the latter, lumbar puncture may be indicated to reduce intracranial pressure. If collapse occurs at the crisis, stimulants should be given.

RAT-BITE FEVER

Synonyms.—Sodoku; Sokoshio; Rat-bite Disease.

Definition.—A chronic relapsing type of fever following the bite of rats, and due to the *Spirillum minus* (Carter, 1887); it is characterised clinically by a return of the inflammation in the healed wound, lymphangitis, adenitis, rigors, fever and a macular or papular purplish rash.

Ætiology.—The disease is common in Japan, China and Bombay, and cases have been reported from France, Italy, Spain, Britain, East Africa, West Indies and Australia. Any one bitten by an infected rat may acquire the disease. In man the spironemata were found in the bitten tissues and in the lymph glands by Futaki; they are demonstrable with difficulty in the peripheral blood, appearing as thick, short forms (3 to 6 microns), which on cultivation increase in length (20 microns). About 3 per cent. of house rats in Japan are carriers, and after experimental inoculation spirilla are present in the blood for the first fortnight of infection.

Pathology.—In human cases, degenerative changes in the liver and kidneys have been reported, while animals show congestion and swelling of the lymph glands and spleen.

Symptoms.—After being bitten the wound heals up in an ordinary manner, but in from two to six weeks pain and swelling appears at the site of the old bite and the scar breaks down. The lymphatics draining the area of the bite become inflamed, with enlargement of the corresponding glands; a definite ulcer may now mark the site of the bite, with an angry inflammation spreading away from it, and small vesicles may break out around it. When this has continued for some time, general symptoms make their appearance; the temperature rises to 103° F. or over; there may be rigors, vomiting, nausea, severe headache, joint pains, diarrhoea and general malaise. A specific rash then usually appears as dusky-coloured, purplish red spots, or a coloured, patchy erythema over the limbs, trunk and face, which lasts for some time and slowly disappears. After remaining high for three to eight days, the temperature drops, often by crisis, and the symptoms generally ameliorate. After a varying period of time the first relapse appears with a return of the former symptoms. Pyrexia then disappears, only to be followed by further relapses, which in some of the reported cases have continued for months or even years. Considerable debility follows the attacks, and finally the patient may pass into a very poor state of health. A transient or permanent nephritis

may result, and exophthalmos and paresis have been seen in some cases. Ultimately the infection tends slowly to disappear.

Diagnosis.—The history of rat-bite, the local lesion associated with lymphangitis and adenitis, the specific rash, and recurrent fever are typical. In some ways the disease resembles syphilis, but the Wassermann reaction is negative. Spirilla are difficult to demonstrate in the peripheral blood, and white rats or mice should be inoculated with human blood.

Prognosis.—With modern treatment this is quite good, but previously it was not so, many cases continuing with chronic symptoms for years. A mortality of 10 per cent. has been given by some authors.

Treatment.—Arsphenamine or some of its derivatives should be given, commencing with doses of 0.3 gram. One or two injections are usually sufficient to abolish completely all the symptoms and bring about a permanent cure.

N. HAMILTON FAIRLEY.

E. PROTOZOAN INFECTIONS

MALARIA

Synonyms.—Ague; Paludism; Remittent, Intermittent, Marsh or Jungle Fever.

Definition.—A protozoal disease of man caused by various species of *Plasmodium* which infect the red corpuscles and give rise to periodic fever, splenomegaly and anæmia; transmission is by anopheline mosquitoes.

HISTORICAL.—Malarial fevers were recognised by Hippocrates in the fifth century B.C., while in the time of Cæsar, Varro suggested they might originate from swamps. In the Middle Ages, people in Europe suffered severely from the ague, being saved from its ravages by cinchona bark brought back from Peru by the Jesuits in the first half of the seventeenth century. This remedy also enabled Sydenham and other physicians to separate malaria from other fevers. Laveran (1880) discovered both the parasite and the phenomenon of flagellation in shed blood, but differentiation into the three species was not made until later. Manson (1894) formulated the hypothesis of mosquito transmission, inducing it from the phenomenon of flagellation of the male gamete, but he thought that man acquired the disease from infected mosquitoes via water and not by biting. McCallum (1897) recognised the fertilising function of the "flagellating body." Ross (1898) worked out the correct transmission and developmental cycle of bird malaria (*Proteosoma*) in culicine mosquitoes, and having previously observed the partially developed oöcysts of human malaria in dappled winged mosquitoes (anophelines) he predicted a human life cycle similar to that observed in bird malaria. Later in the same year, Grassi, Bignami and Bastianelli (1898) observed the complete development of malignant tertian malaria in *Anopheles maculipennis* and transmitted the disease to man by the bite of infected mosquitoes.

Ætiology.—Two distinct ecological problems are presented in malaria—the parasite and its environment, on the one hand, and the anopheline mosquito and its environment on the other.

Malignant tertian (M.T.) or subtertian malaria greatly predominates in the tropics, and benign tertian (B.T.) in temperate zones, while in the subtropics both these forms and quartan malaria may occur. The last has a patchy distribution. Islands such as Fiji where anophelines are absent are free from malaria. Malaria is not found between latitudes approximately 60° north and 30° south because temperature considerations limit its extension. The critical temperature determining development in the mosquito is about 60° F., and this must be maintained sufficiently long to allow the sexual cycle to be completed. In Europe the disease disappears at about 3000 feet, and in India and Africa at 6000 feet. Seasonal prevalence, which is not marked near the equator becomes so farther from it. Throughout South-East Europe the malaria season extends approximately from June to October.

All races contract malaria, but European and Chinese are regarded as being more susceptible than Negroes and certain aboriginal races. Apparent racial immunity is generally acquired in childhood, from long-continued infection. In endemic areas infection is commonest in children, but as a result of repeated infections both children and adults gradually acquire a certain degree of immunity (premunition), which only persists as long as parasites persist. In avian and simian malaria this has been shown by Taliaferro and others to depend on a specific enhanced phagocytic function and hypertrophy of the reticulo-endothelium in the spleen, liver and other organs.

M.T. malaria is responsible for most epidemics, the factors necessary being a sufficient number of (1) good gametocyte carriers, (2) efficient anopheline vectors, and (3) none-immune individuals.

In war when large bodies of "unsalted" troops have had to fight in hyperendemic areas of malaria, such as Tropical Africa and New Guinea, big epidemics have resulted in which a large proportion of the Forces involved have become rapidly infected. The initial breakdown was caused by *P. falciparum* in about 80 per cent. of cases, but after treatment such individuals, when they relapsed, were found to be infected with *P. vivax*. In civilian life the tropical aggregation of labour may lead to similar consequences. Regional epidemic malaria, of which the Punjab epidemic (1908) and the Ceylon epidemic (1934) are examples, is dependant on the development of a large number of non-immunes consequent on a sequence of healthy years, followed by undue exposure to anophelism. Flood or drought may be the factors leading to an increase in the local anopheline vector. In the Ceylon epidemic failure of the crops and the resulting famine further lowered individual resistance, and within seven months some 80,000 people died of M.T. and B.T. malaria.

Parasitology.—The malaria parasites are protozoa belonging to the class *Sporozoa*, genus *Plasmodium*. There are several distinct species affecting man: quartan malaria, caused by *Plasmodium malariae* (Laveran, 1881); benign tertian (B.T.), due to *Plasmodium vivax* (Grassi and Feletti, 1890); malignant tertian (M.T.), caused by *Plasmodium falciparum* (Welch, 1897); and a tertian malaria, due to *Plasmodium ovale* (Stephens, 1922.) A fifth form, *Plasmodium tenue* (Stephens, 1914), has been described, but its species status remains doubtful. Man is also susceptible to experimental infection with *Plasmodium knowlesi*, a plasmodial parasite of monkeys.

Asexual cycle in man (endogenous cycle; schizogony). The sporozoites,

after inoculation by the mosquito, disappear within a few minutes from the blood, which for the next five days loses its infectivity even when injected intravenously in large amounts into a susceptible individual. It has been suggested that during this period the sporozoites are undergoing an exo-erythrocytic cycle within reticulo-endothelial or macrophage cells, but this has not yet been proved. About the seventh day the blood regains its power of infectivity, and within a few days intra-corporal parasites are demonstrable microscopically.

The asexual growing forms (trophozoites) at first have their cytoplasm arranged somewhat crescentically around a central vacuole and contain one or more small masses of chromatin. With increase in the size of the vacuoles definite ring forms result. As the parasite enlarges hæmoglobin (malaria pigment) appears, and medium-sized amœboid-like forms are produced. As the parasite reaches maturity pigment collects centrally and the chromatin divides into two, four or more portions each surrounded by a mass of cytoplasm; this is known as the sporulating, segmenting, or rosette form or the schizont. The mature schizont consists of a variable number of young forms (generally 8 to 16), known as merozoites, which soon escape into the plasma and subsequently invade fresh red cells restarting the cycle.

Sexual cycle in the mosquito (exogenous cycle; sporogony). In addition to these asexual forms produced during schizogony in man, certain sexual forms (gametocytes) are liable to appear in the blood following a bout of malaria fever. These are large round or oval bodies filling and expanding the erythrocytes in benign tertian infections, and crescentic-like bodies in malignant tertian malaria; when these crescents are inhibited by suitable anophelines the corpuscles are ruptured and they revert to a circular form in the mosquito's stomach. Here the male gametocytes produce flagella (microgametes), which separate off (exflagellation) and subsequently penetrate the female gametes (macrogametes) produced by maturation from macrogametocytes. The resulting body, known as the zygote, develops into the elongate travelling vermicle or ookinete which penetrates the stomach wall: here it becomes circular in outline and develops into an oöcyst which finally becomes packed with sickle-shaped sporozoites and causes a cyst-like protrusion on its outer surface. These oöcysts subsequently rupture and sporozoites escape into the body cavity (hæmocoele) and ultimately make their way to the salivary gland. When the mosquito bites, the sporozoites pass with the salivary secretion into the new host (see Asexual Cycle in Man). The time taken to complete this cycle varies from 8 to 20 days, temperature conditions being an important factor in rate of development.

Mosquito vectors of malaria. It is not every anopheline mosquito which can transmit malaria successfully. Perhaps the best-known transmitter of malaria is *A. maculipennis*, which is nocturnal in habit, and has been specially studied in Europe and the Eastern Mediterranean. Hackett, Misseroli and others have shown that *A. maculipennis* is not a uniform species, but is divided into "biological races" or varieties. These races cannot generally be distinguished either as adult or larvæ, but only by their egg characteristics. The breeding grounds, sexual behaviour and feeding habits differ. Thus, the race called *elutus* bites man for choice, and is a dangerous carrier of malaria; other races, like *typicus* and *messeeæ*, bite cattle for choice, and therefore are much less dangerous to man. The larvæ of *elutus* need traces

of salt in water, and for this reason they tend to have a costal distribution. In the Balkans, malaria of the plains is mainly transmitted by *A. maculipennis* var. *clutus*, whereas malaria of the hills is solely transmitted by *A. superpictus*, which especially breeds in running mountain streams with rough rocky beds. *A. bifurcatus*, which in Europe has little relationship to malaria, used to be a common source of this disease in Palestine where it bred in underground cisterns, inside towns and villages, and produced much urban malaria. *A. culicifacies*, which transmits malaria in Ceylon, breeds in the dry season in trickles of water and water-holes in the empty beds of rivers. It follows that the mosquito vector should be carefully studied in every country and special local methods devised for its extermination. Drainage of swamps, land reclamation, elimination of breeding sites and destruction of larvæ by D.D.T., oiling, etc., are essential factors in malaria control.

There are many different vectors in other parts of the world, some of the more important of which are: *A. albimanus*, tropical America; *A. quadrimaculatus*, United States; *A. funestus*, tropical Africa and India; *A. gambiae* (costalis), tropical Africa, Arabia and Brazil; *A. culicifacies*, India and Ceylon; *A. stephensi*, breeding in wells in cities in India; *A. maculatus*, India, South-East Asia and Netherlands East Indies; *A. minimus*, India, Burma, etc.; *A. sundaicus* (ludlowi), the dangerous brackish water breeder in the Far East; *A. punctulatus* var. *typicus* and *A. punctulatus* var. *moluccensis*, New Guinea and New Britain which breed in man-made sites such as footprints, ruts from vehicles and borrow pits; and *A. punctulatus* var. *moluccensis* and *A. annulipes* in Northern Australia.

The danger of the introduction of new anopheline vectors into other countries is illustrated by recent history of a most dangerous, African vector, *A. gambiae*. This species reached Brazil, probably by aeroplane or destroyers, in 1930, and was followed by severe outbreaks of malaria, the epidemic in 1938 causing 50,000 cases. Recently *A. gambiae* has appeared in the Nile Valley in Egypt, where the usual vector is *A. pharænsis*.

Parasites in blood smears.—All forms of *P. vivax*, *P. malariae* and *P. ovale* are met with in the peripheral blood, but in malignant tertian malaria owing to sporulation in the internal organs, generally only the small rings and large crescents of *P. falciparum* appear. Blood smears are stained by Leishman's or Giemsa's stain, while Field's rapid staining method gives excellent results in thick films in routine diagnosis. The following points assist in differentiating the different species. *Ring forms.* The rings of *P. falciparum* occupy about one-sixth of the cell, which may show Maurer's clefts. They are often fine and hair-like, and show irregular or flattened marginal forms. Two chromatin dots and multiple infection of the same corpuscle may occur. Occasionally this is seen with *P. vivax*. The rings of *P. vivax* and *P. malariae* occupy about one-third of the cell, are larger and contain more cytoplasm, but the species cannot always be determined if only ring forms are present (Wenyon). *Partly grown forms.* In *P. vivax* the infected corpuscle is enlarged, Schüffner's dots are present, and the parasites are of irregular shape and contain light brown pigment. With *P. malariae* there is no enlargement of the corpuscle, the pigment is dark brown or black, band forms are common, and Ziemann's stippling may be demonstrated in the red cells by special staining. *Adult forms.* In *P. vivax* and *P. malariae* the schizonts have 16 and 8 merozoites respectively, in contrast with which the gametocytes have a single nucleus

and a different distribution of pigment and chromatin. *P. ovale* somewhat resembles *P. malariae* morphologically, but infected corpuscles show Schüffner's dots, and are often oval or distorted in shape with serrated edges.

Pathology.—Clinical.—In severe and persistent infections there is considerable blood destruction. The intra-corpuscular parasite digests hæmoglobin utilising the globin as pabulum and depositing the hæmatin moiety as malaria pigment (hæmozoin). Though free hæmoglobin is not generally detected spectroscopically in plasma collected during or after the paroxysm, Schumm's test for methæmalbumin is often positive indicating that corpuscular lysis with liberation of extracorporeal hæmoglobin is occurring. Hæmatogenous bilirubin also tends to be increased, the indirect Van den Bergh reaction varying from 1.0 to 8.0 units. Hyperbilirubinæmia is responsible for the hæmolytic icterus, and pleocholia observed in severe and persisting infections. The total serum proteins are reduced, mainly owing to the decrease in the serum albumin: pseudoglobulin is reduced and euglobulin increased. The alkali reserve may be moderately reduced. The sedimentation rate is usually increased.

In untreated infections, especially M.T., severe anæmia may rapidly develop. Before the disease has become chronic, anæmia in uncomplicated cases is generally normocytic in type. The blood picture may show polychromasia, anisocytosis, poikilocytosis, punctate basophilia, and occasionally normoblasts. Hypochromia may develop later. Leucopænia with a left shift occurs early, followed later by a monocytosis; a monocyte count of 15 per cent. or over is suggestive of malaria infection.

The urine may be dark brown in colour due to urobilin. Albuminuria is not uncommon, and casts and other evidences of nephritis may be found in quartan malaria. Bile pigments and bile salts generally indicate malaria hepatitis. Delayed excretion of bromsulphalein and other tests for liver function may indicate liver damage.

Morbid anatomy.—In a fatal case of *acute pernicious malaria* the spleen is enlarged and congested, blackish-red in colour, with soft, dark pulp. The liver is also congested and enlarged, while the gall bladder is distended with brownish-black bile. Small hæmorrhages may be present in both these organs. The serous membranes and mucosa of the gastro-intestinal tract are congested and leaden-coloured and may show small hæmorrhages. Lipoid and fat may disappear from the cortical layer of the suprarenals. The heart muscle is often pale and flabby, showing cloudy swelling or actual fatty degeneration; ecchymoses on the myocardium and pericardium are not infrequent. The marrow of the short bones is dark or chocolate coloured, while that in the long bones presents a variable picture depending on the degree of hyperplasia. In cerebral malaria the meninges are hyperæmic, the cortex is a smoky or leaden-grey colour, while punctiform hæmorrhages are scattered through the white matter.

The *microscopic* study of the organs in fatal cases has done much to explain the varied clinical manifestations of the disease. Thus:

(1) Pigmentation of the serous membranes and internal organs is caused by malaria pigment (hæmozoin) contained in parasitised red cells in the capillaries, in macrophages, and R.E. cells, particularly in the red pulp of the spleen or the sinusoids of the liver and bone marrow. A fine, yellow granular pigment, giving the Prussian blue reaction for iron with ferrocyanide, is also

found in the parenchyme cells of the liver, spleen and kidneys. (2) The early enlargement of the spleen and liver is mainly due to acute congestion, and in the case of the spleen to commencing hyperplasia of R.E. cells of the red pulp, some of which may show toxic degeneration. (3) Degenerative changes (possibly due to "malarial toxin") are manifested in the polygonal hepatic cells, the convoluted tubules of the kidney, the cortical cells of suprarenal glands, and capillary endothelium giving rise to multiple hæmorrhages. (4) Capillary blockage by parasitised corpuscles leading to local tissue anoxia, small areas of hæmorrhage and necrosis, possibly followed by neuroglial proliferation and the formation of so-called "malaria granulomata." Proliferative changes of the reticulo-endothelium in the capillary areas of the brain leading to granulomata are also described. In *chronic malaria* in which repeated infection has occurred for years the spleen ("ague cake") is very enlarged and hard, the capsule is thickened, and often adhesions bind it firmly to the diaphragm, etc.; sometimes the adhesions are calcified. Microscopic section shows great hypertrophy of the R.E. cells, which often contain malaria pigment, atrophy of the malpighian bodies and lymphoid tissue generally, and extensive fibrosis.

Symptoms.—The natural history of malaria in the untreated or ineffectively treated patient includes (i) an incubation period, (ii) a stage of primary fever, which, if the patient survives, is followed by, (iii) a period of latency and, (iv) a stage of recrudescences or relapses.

(i) INCUBATION PERIOD

In malignant tertian and benign tertian malaria this is generally about 10 to 12 days, but varies from 8 to 23 days. In quartan malaria it is often longer. Occasionally in B.T. infection the primary fever may be suppressed and the incubation period extended to as long as nine months; this may also happen in individuals taking suppressive anti-malaria drugs at the time of infection.

(ii) PRIMARY FEVER

At the onset of primary fever, parasites are often very scanty and may only be found after prolonged search. The onset of fever is undoubtedly related to segmentation, but it is not dependant exclusively on parasite density; host reaction is another factor. There is often an initial period of continuous, remittent or intermittent fever which lasts a variable period; this is especially characteristic of M.T. infection. Intermittent fever generally becomes established at an earlier stage in B.T. than in M.T. primary fever, and though the temperature may be quotidian at first it later becomes tertian in type. But exceptions occur, and in some cases the primary B.T. fever may be tertian at onset and quotidian later. In quartan malaria, which particularly affects children, a quartan periodicity tends to be established early, even in primary fever, and in untreated individuals typical paroxysms of ague may persist for many months before the latent phase becomes established. If there are interpolated attacks due to multiple strains, a double or triple quartan chart may ensue; the last is associated with quotidian fever.

In the ordinary septicæmic type, the onset is either sudden or insidious, with prodromal symptoms, such as tiredness, stiffness of the neck muscles, pains in the muscles and bones and anorexia. Fever, when it appears, is generally associated with headache, backache, aching pains in the bones, malaise, and fatigue. Shivering is often absent, especially in M.T. infections, while nausea, anorexia and vomiting are common.

The spleen though always increased in size is frequently not palpable in the early stages of the disease; later, it is felt as a tender soft mass below the left costal margin, moving on respiration. Splenic pain may be troublesome. The liver is enlarged as often as the spleen in primary malaria; it is frequently tender and its edge may be palpated below the right costal margin moving with respiration. The gall bladder may also be distended, though this is rarely demonstrable. Herpes on the lips and face is common and should suggest the possibility of malaria. Mild bronchitis is another suggestive sign, while abdominal pain, constipation or diarrhoea are not infrequent. There may be signs of blood destruction, including (1) anæmia, (2) hæmolytic jaundice, (3) polycholia with bilious vomiting and chocolate-coloured stools, and (4) brown urine due to urobilinuria.

Prior to the spleen becoming palpable, influenza, dengue, sandfly fever, scrub typhus or enterica may be suspected. After the spleen is demonstrably enlarged diseases associated with splenomegaly, such as typhoid, paratyphoid, undulant fever, relapsing fever, kala-azar and trypanosomiasis need differentiation. Amœbic abscess, cholecystitis, pyelitis, subacute bacterial endocarditis, or occult sepsis may simulate malaria. In bacterial infections there is often a polymorphonuclear leucocytosis and the febrile attack comes on later in the afternoon or evening than is customary in malaria. When jaundice complicates the picture infectious hepatitis, yellow fever and leptospirosis may need differentiation. So-called typho-malaria may occasionally develop. Here the temperature chart, splenomegaly, hæmorrhage from the bowel or epistaxis, and the development of the so-called "typhoid state" with low muttering delirium may suggest typhoid until parasites are found in the blood. Blood cultures should invariably be made to exclude enterica in such cases as malaria and typhoid may occur together.

Bilious remittent fever is a well-recognised type, characterised by remittent fever, epigastric discomfort, bilious vomiting, chocolate-coloured stools, and urobilinuria. The spleen and liver are both enlarged and tender, and the skin and scleræ show icterus. The jaundice may be caused by excessive blood destruction or by toxic degeneration of hepatic cells; in the latter case bile pigment and/or bile salts appear in the urine. Bilious remittent fever may be a manifestation of primary or recrudescing M.T. infection.

Acute pernicious malaria.—Apart from the general septicæmic features induced by parasitæmia, and the anæmia and jaundice resulting from blood destruction, there are a number of manifestations classified as acute pernicious malaria, which are mainly dependant on internal sporulation and localised blockage of the capillaries by *P. falciparum* in different organs, such as the brain, heart, intestines and spleen by parasitised corpuscles, which adhere to one another and to the capillary endothelium. This phenomenon is peculiar to *P. falciparum* infections, and is chiefly responsible for the diverse symptomatology of M.T. malaria. Its onset may be suspected if hyperinfection be present. Hyperinfection is diagnosed if more than 5 per cent. of

erythrocytes are infected, if more than 5 per cent. of infected corpuscles contain 2 or more parasites, and if pigmented asexual forms of *P. falciparum* are demonstrable in blood films. In extreme cases, 30 per cent. of the corpuscles may show parasites. The chief forms of acute pernicious malaria are as follows:

1. *Cerebral*.—Such patients may develop coma, convulsions, paraplegia, hemiplegia, aphasia, meningismus or hyperpyrexia. Cerebro-spinal fever may be suspected, or the condition be diagnosed as primary heat stroke. The coma may come on rapidly, or be preceded by drowsiness and stupor. In some instances there is great excitability and maniacal and suicidal tendencies may develop; alcoholism or lunacy may be diagnosed with disastrous results. Generally the face is suffused, the pupils contracted and the reflexes modified; increased deep reflexes and extensor plantar responses are common. Malaria coma has to be distinguished from cerebral and pontine hæmorrhage, uræmia, diabetic coma and alcoholic or opium poisoning. The blood practically always contains parasites. Lumbar puncture shows a clear fluid perhaps under increased pressure; a pleocytosis may be found, especially if meningitic symptoms are present.

2. *Algid*.—The patient presents the picture of severe shock and peripheral circulation failure. There is a Hippocratic facies, the skin is cold and covered with clammy sweat, the respirations shallow, the pulse rapid, thready and weak, and the blood-pressure very low. Vomiting, diarrhoea and epigastric pain are not uncommon. Though the skin temperature is low the internal temperature is often high. Parasites are plentiful in the peripheral blood smears.

3. *Cardiac*.—There is breathlessness, cyanosis, congestive failure and sometimes sudden death. Degenerative myocardial changes and blocked capillaries are the basis of the syndrome.

4. *Gastro-intestinal*.—In gastric malaria there is epigastric discomfort and tenderness, severe bilious vomiting, and occasionally hæmatemesis. Gastric ulcer may be diagnosed. In the small intestinal type, cholera may be simulated but the fluid stools are brown, not colourless. Where the large bowel is involved the stools may contain blood with or without clear mucus; the mucus, however, does not contain cellular exudate, and sigmoidoscopy fails to show ulceration though congestion and small mucosal hæmorrhages may be observed. Occasionally large hæmorrhages occur. Bacillary dysentery or intrusception may be erroneously diagnosed.

5. *Abdominal*.—Abdominal discomfort and pain are not infrequent in primary M.T. malaria. If associated with vomiting and tenderness over the liver, gall bladder, epigastrium or cæcum, an erroneous diagnosis of cholecystitis, gastric ulcer, pancreatitis, or appendicitis may be made. In malarious areas a careful blood examination should invariably precede any abdominal operation; only by so doing can serious mistakes be avoided.

6. *Purpuric*.—Petechial or purpuric skin eruptions, epistaxis, hæmatemesis, hæmoptysis, malæna, hæmaturia, or vaginal hæmorrhages are occasionally encountered.

7. *Renal*.—Albuminuria is common, and in severe infections may be associated with renal casts and red blood cells in the urine. Toxic changes in renal epithelium are probably responsible.

It is to be noted that acute pernicious malaria may also occur in M.T.

recrudescences as well as in primary fever. If the patient survives the primary attack and has not been cured, a period of latency supervenes.

(iii) PERIOD OF LATENCY

Fever and clinical symptoms are absent, though enlargement of the spleen may be found. Though parasites cannot be demonstrated even in thick films, malaria fever generally results when blood is subinoculated into a susceptible individual. Persons with latent malaria are therefore unsuitable donors for blood transfusion. If the latently infected individual be injected with blood containing his own strain of parasites, malaria fever and parasites fail to develop (premunity); but if he be injected with another strain of the same species or with another species of *Plasmodium*, a typical attack of malaria results. This specificity is probably dependant on specific opsonins, which prepare parasitised cells for phagocytosis by hypertrophied R.E. and macrophages. This phase of latency may last from a few weeks to many months before fever reappears. Certain factors such as chill, wetting, exposure, exhaustion, blood loss, anæsthetics, surgical trauma and high altitude flying (anoxia), may upset the biological balance between host and the parasites and induce recrudescence or relapse.

(iv) RECRUDESCENCES AND RELAPSES

This stage is characterised by periodic intermittent fever and typical ague attacks with cold, hot and sweating stages. In M.T. and B.T. malaria pyrexia occurs on alternate days, in quartan fever every fourth day. Onset of fever is generally in the morning or early afternoon.

In *M.T. malaria*, pyrexia generally recurs in from one to six weeks, and under these circumstances is classified as a recrudescence rather than a relapse. The fever, which at onset may be quotidian in type, soon establishes tertian periodicity. The temperature rises less abruptly and is generally lower than in B.T. ague, and chilliness rather than a rigor is characteristic. The hot stage tends to be more prolonged and the sweating stages less intense, while paroxysms last longer, *i.e.* 12 to 24 hours. Fatigue, backache, headache, pains in the limbs, anorexia, nausea and vomiting, which may be bilious in type, are common. If the fever is uncontrolled by treatment the spleen becomes rapidly enlarged and tender, and hepatomegaly, hæmolytic anæmia and perhaps jaundice develop. Unless the individual has been taking atebirin or quinine for suppressive purposes, parasites are readily demonstrated in recrudescences even at the beginning of fever; as in primary fever hyperinfection and acute pernicious manifestations may develop with fatal results. Unless cured, liability to relapse persists for about six months.

As has been mentioned, acute pernicious malaria may occur in M.T. recrudescences.

In *B.T. malaria*, a longer period generally intervenes between primary fever and recurrences, *i.e.* relapses rather than recrudescences are the rule. They are characterised by typical attacks of tertian ague similar to those seen in the primary attack.

Cold Stage.—The patient feels listless and develops headache, backache, pains in the limbs and chilliness. Then the rigor begins. He lies curled up

in bed with chattering teeth, shivering violently. The face is pinched and the skin cold and blue. Blankets and rugs are applied in an effort to keep warm. Nausea and vomiting are not uncommon. After $\frac{1}{2}$ to 2 hours the axillary temperature rises rapidly, attaining a height of 103° to 106° F.

Hot Stage.—The skin becomes burning hot and bedclothes are discarded. Fever is now high, the face is flushed, the pulse is rapid, the carotids throb and the head aches. In severe cases delirium may develop. This stage persists for 8 to 10 hours.

Sweating Stage.—The skin now moistens, profuse sweating ensues, pains and headaches disappear, the pulse slows, the tongue becomes moist, the temperature falls, slowly at first and then more rapidly, until a normal or subnormal level is reached. At the end of the attack the patient feels reasonably well.

Splenomegaly, anæmia and herpes are characteristic of recurrences, especially if fever is not early controlled by treatment. Usually relapses tend to get milder, with progressively longer intervals between. Liability to relapse may persist for 2 to 3 years.

In *Quartan malaria* relapses, the paroxysm is shorter than in B.T. ague, (6 to 10 hours), and the temperature tends to be higher; temperatures of 105° to 106° F. are common. Spontaneous recoveries are few, and long periods of latency occur between relapses. Infections may persist for seven years or longer.

Malaria cachexia.—In old-standing cases, especially if there are repeated infections with different strains and species of parasite and inadequate treatment, the spleen becomes stoney hard and very enlarged, and perisplenitis may give rise to severe splenic pain and discomfort. Cachexia, anæmia, a dirty earthy-coloured skin, digestive disturbances, enlargement of the liver, physical inertia, œdema of the feet and ankles, deterioration of memory and lack of concentration may develop. There may be long intervals of apyrexia or subnormal temperature, but transient bouts of fever may occur in which parasites are demonstrable in the blood for a short time only.

The clinical picture at this stage is often complicated by the effects of dietary deficiency. Thus, (1) hæmolytic macrocytic anæmia may follow lack of good biological protein and possibly vitamin B complex as in Macedonia, (2) microcytic hypochromic anæmia occurs if there is lack of iron in the diet, as in parts of India; ankylostomiasis here may also be a complicatory factor, and (3) neuritic manifestations may follow deficiency in B_1 .

Complications and Sequelæ.—Complications include herpes of the lips, nose, eyelids and cornea, supraorbital neuralgia, anæmia, malaria hepatitis, pigment gallstones, nephritis, with or without œdema and ascites (especially encountered in quartan infections in childhood), abortion and premature birth. Ocular complications include conjunctival hæmorrhage, corneal ulceration, keratitis, iritis, choroiditis, retinal hæmorrhages, optic neuritis and malaria amblyopia. Dendritic corneal ulcers are the most common ocular complication, the lesions being generally superficial, seldom penetrating into the deeper corneal layers. The mild lesions clear up in two to four weeks, the more severe taking months to heal. They frequently develop from herpetic lesions but may also arise without previous corneal involvement. Malarial amblyopia may follow cerebral malaria; the discs are a cherry-pink colour with blurred edges, in contrast to the pale or white

discs observed in quinine amblyopia. Retinal hæmorrhages may also follow cerebral malaria, but they are most commonly associated with severe anæmia.

Splenic complications include (1) perisplenitis, (2) subcapsular hæmatoma, (3) rupture, and (4) torsion of the pedicle. Rupture of the spleen is an important complication which may occur in either acute or chronic malaria. It may follow trauma or such acts as sneezing or straining at stool. The onset may be sudden or gradual; in the latter case a small tear may lead to a subcapsular hæmatoma which may rupture later. Tears generally occur on the visceral side close to the hilum. A subcapsular hæmorrhage may be associated with severe splenic pain, and if a subcapsular hæmatoma impinges on the diaphragm it may produce (1) left shoulder pain, (2) elevation of the left diaphragmatic leaf, and (3) evidence of collapse or consolidation involving the lower lobe of the left lung. When rupture occurs through the capsule into the peritoneal cavity there is local evidence of splenic and peritoneal involvement combined with that of internal hæmorrhage. In cases with chronic malarial splenomegaly ("ague cake spleen"), dislocation of the spleen or torsion of its pedicle may occur. Both rupture and twisting of the pedicle necessitate immediate operation.

The most important sequela of malaria amongst Europeans in the tropics is blackwater fever, which is described separately.

Certain mental conditions, including psychoses, aphasia, sexual impotence, and loss of memory, have been described as sequelæ of long-continued malaria. Many of these are undoubtedly functional in origin, and associated with the mental stresses or strains of life in the tropics. Others may possibly have an organic basis and be related to the formation of malaria granulomas in the subcortical layer.

Diagnosis.—Malaria is an arch simulator, and in acute pernicious malaria or primary fever before periodicity has become established, and splenomegaly and anæmia have developed, a certain diagnosis can only be made by demonstrating parasites. Owing to the absence or scarcity of demonstrable parasites in the early stages, thick as well as thin blood films should always be examined, and several examinations should be made before malaria can be excluded. Anti-malarial drugs should never be administered before collecting the specimen. If patients have been taking mepacrine or quinine for suppressive purposes, the difficulty in finding parasites is further increased. When acute pernicious malaria is suspected it is better to take blood films and commence treatment without waiting for the laboratory report.

Outstanding considerations in making a diagnosis are: (1) Blood examination for parasites. Polychromasia, a leucopænia with a left shift and mononucleosis of 15 per cent. or more are suggestive of malaria infection. (2) Febrile attacks of typical ague having a tertian or quartan periodicity. (3) Demonstrable enlargement and tenderness of the spleen and/or liver. (4) Evidence of blood destruction, including anæmia, hæmolytic jaundice, and urobilinuria. (5) Herpes on the lips and face. (6) The therapeutic test. It is rare to find uncomplicated malaria fever persist for more than four or five days after adequate specific drug therapy has been instituted. In doubtful cases the blood concentration of mepacrine or quinine should be determined.

In the tropics the differential diagnosis largely depends on geographical consideration and what fevers are prevalent at the time. As the subject has

already received detailed consideration in the section on Symptoms, it need not be further commented on here.

Prognosis.—Malaria is the chief cause of death in the tropics, being specially serious (1) in pregnancy causing abortion, premature birth, and possibly death of the mother, (2) in young children and non-immune Europeans before premunity has developed, and (3) in the aged. In M.T. infections the prognosis is dependant on early diagnosis, and the speed with which appropriate treatment is instituted. Hyperinfection, with or without coma or cardiac failure, accounts for most deaths. Blackwater fever or rupture of the spleen may also prove fatal. Death in B.T. and quartan malaria is generally associated with intercurrent diseases, *e.g.* pneumonia, dysentery, ankylostomiasis and anaemia, or malnutrition or pregnancy. In the absence of specific drug treatment, M.T. infections are frequently fatal, while those showing acute pernicious manifestations invariably die. The death-rate with appropriate treatment should be low. In troops infected while fighting in hyperendemic areas in New Guinea, not more than 1 in 3000 cases died of uncomplicated malaria; this was especially remarkable, as they practically all suffered from M.T. malaria and many had B.T. infections as well.

Treatment.—**PROPHYLACTIC.**—Tropical residents should live in mosquito-screened houses whenever possible, and always use mosquito nets at night. After sunset appropriate clothing should be worn, including mosquito boots or some form of ankle protection, while mosquito repellent lotion or cream should be applied to exposed parts. Destruction of adult vectors by the use of pyrethrum and D.D.T. spray in bungalows is important. The obliteration of breeding-places and larval destruction is often indispensable factors in malaria control.

Suppressive drug treatment.—In human malaria no true causal prophylactic drug, *i.e.* one lethal to sporozoites is known. Quinine in a dosage of 10 grains daily may suppress B.T. infections, but in hyper-endemic areas it fails to suppress heavy infections with certain strains of *P. falciparum*. Mepacrine in a dosage of 0.1 g. daily is definitely superior to quinine in these respects, since it suppresses B.T. infections completely, and both suppresses and cures M.T. infections, provided the daily dosage be continued for four weeks after leaving the malarious area. This has been proved experimentally in man infected with virulent New Guinea strains of *P. vivax* and *P. falciparum*, and probably holds for strains in other parts of the world. Toxic manifestations are extremely rare in healthy adults taking 1 tablet (0.1 g.) of mepacrine daily. Yellow staining of the skin often follows, but this is quite harmless and has no relationship to jaundice.

CURATIVE.—The best-known anti-malarial drugs are quinine, mepacrine, and pamaquin. Arsenic compounds have distinct therapeutic action on the schizonts and gametocytes of *P. vivax*.

Quinine.—This is a crystallisable alkaloid obtained from cinchona bark; chemically it is a quinoline compound of complex molecular structure which has recently been synthesised. Various salts are available, the insoluble sulphate and the soluble bihydrochloride being mainly used. Quinine exerts schizonticidal action on all human species of plasmodia, and is gameticidal for all except *P. falciparum*. Regarding dosage, opinions differ, but in primary malaria it is sound therapy to give 30 grains of the bisulphate for the first week,

20 grains for the second, and 10 grains for the third. The drug is best given in a mixture in $\frac{1}{2}$ oz. doses as follows : Quinine sulph. gr. X ; Acid sulph. dil. mx ; Syr. simplex dr. 1 ; Aq. chlorof. ad oz. $\frac{1}{2}$. If vomited, the dosage should be repeated. In M.T. cases the mixture can with benefit be given four times daily for the first three days, but with B.T. infections this is unnecessary. Children bear quinine well, the dosage being appropriate to age. Toxic effects include tinnitus, visual and gastric disturbances, deafness, and amblyopia. Idiosyncrasy may result in severe erythematous and urticarial rashes.

Intravenous quinine therapy is often a life-saving procedure. The chief indications are : (1) where the patient cannot swallow or has severe vomiting or diarrhoea ; (2) hyperinfection ; (3) acute pernicious malaria, especially if there are cerebral symptoms, hyperpyrexia, cardiac or algid manifestations ; (4) persistence of asexual parasites, and failure of oral quinine to control the temperature after four days' medication.

The injection consists of ten grains of bihydrochloride of quinine in ten c.c. or more of isotonic saline solution. Precautions to be observed are (1) sterility of the solution, (2) adequate dilution, and (3) slow injection. As regards the third, at least three minutes should be taken, the reason being that too rapid injection may lead to marked lowering of blood-pressure and collapse. Adrenalin, however, should never be employed with the idea of preventing a fall in blood-pressure. When time will not be lost it is desirable to dilute the quinine further by increasing the volume of saline injected.

Aseptic venous thromboses may follow such injections but they are harmless, treatment being unnecessary. No fatal results were recorded in many thousands of such injections given to troops in New Guinea. Intramuscular injections of quinine should be reserved for those cases in which it is impossible to use the intravenous route. Though effective therapeutically, such injections are painful, cause muscle necrosis, and may produce a chemical or bacterial abscess.

Mepacrine (atebrin ; quinacrine). Mepacrine hydrochloride is a synthetic acridine derivative which compares very favourably with quinine inasmuch as it is a good schizonticidal drug and destroys the gametocytes of *P. vivax* and *P. malariae*, but not of *P. falciparum*. The usual dosage advocated has been one tablet (0.1 g.) thrice daily after food for seven days. Though satisfactory in relapsing B.T. malaria, this has proved inadequate in the treatment of primary M.T. malaria. It is now known that to build up an adequate blood concentration of mepacrine, a higher initial dosage should be administered. The following course is more suitable : 0.3 g. thrice daily for the first day, 0.2 g. thrice daily for the second day, 0.1 g. thrice daily for the next four days (total course equals 2.7 g.). Mepacrine in the above dosage is no more toxic than 30 grains of quinine a day. Mild gastro-intestinal symptoms may be occasionally complained of, including nausea, abdominal discomfort and vomiting, but real idiosyncrasy is very rare. Harmless and transient yellow staining of the skin may follow. With this dosage, toxic nervous features are not observed in healthy adults but if it be increased to a total of 2.0 g. in the first 48 hours occasionally toxic psychoses or transient convulsions may result.

Mepacrine hydrochloride and atebrin musonate (0.125 g. equals 0.1 g. mepacrine hydrochloride) can both be used for intramuscular injection in a dosage of 0.2 g. and 0.25 g. respectively and repeated in four hours if necessary.

Indications for their use are similar to those for intravenous quinine therapy ; they should be replaced by oral mepacrine medication as soon as possible.

Pamaquin (plasmoquine ; prequine). This is synthetic quinoline derivative synthesised by Schuleman, and shown by Roehl to destroy M.T. gametocytes but to have practically no effect on the schizonts of *P. falciparum* ; in B.T. and quartan infections it exerts lethal effects on both schizonts and gametocytes. As a gametocide, pamaquine in a dosage equal to 0.01 g. plasmoquine base or 0.02 g. plasmoquine naphthoate thrice daily for three days, or 0.01 g. twice daily for five days, is effective. For this purpose it should be administered about eight to ten days after fever commences, for the gametocyte rise following the primary schizont wave generally begins about this period. Pamaquin is also advocated in conjunction with quinine or following mepacrine to reduce the relapse rate in benign tertian malaria. While it may have such action on certain Indian and Syrian strains of *P. vivax*, it failed to reduce the relapse rate in troops infected with New Guinea strains. When toxic symptoms appear, it is generally found that the dosage of 0.03 g. of plasmoquine base daily has been accidentally exceeded. Headache, colicky abdominal pain, and cyanosis caused by methæmoglobincythæmia may follow pamaquin administration. Toxic hæmoglobinuria has also been described ; it has to be differentiated from blackwater fever in which no methæmoglobin is formed within the corpuscle.

General treatment.—Rest in bed is essential during the febrile period, and is advisable for three days after the temperature reaches normal or longer in cases with primary M.T. fever, or in those with persisting tender enlargement of the spleen. A suitable aperient, such as magnesium or sodium sulphate, is administered at the onset of fever and should be repeated daily if necessary, as constipation should be avoided. During an attack of ague, hot drinks and plenty of blankets are necessary in the cold stage. Cold drinks, an ice cap, and an aspirin-phenacetin mixture decrease discomfort in the hot stage. When the temperature exceeds 104° F., tepid sponging is indicated. Drinks should be sweetened with sugar (4 oz. daily). In the sweating stage, hot drinks are indicated, and bedclothes and pyjamas require changing. During convalescence, a well-balanced diet is essential. A tonic mixture containing iron (Ferri. sulph. grs. iii.) is advisable thrice daily if there is anæmia, and, if it be severe, blood transfusion will accelerate convalescence. When malaria is the cause of the anæmia, administration of anti-malarial drugs is followed by a specific reticulocytosis reaching a maximum some seven to ten days later and, provided that diet is well balanced and adequate in vitamins and blood-forming constituents, blood regeneration is rapid.

Combined treatment.—A rational treatment for Europeans infected with M.T. is as follows : (1) Quinine sulphate mixture (10 grains) three or four times daily for three days. (2) Mepacrine, 0.2 g. thrice daily on the fourth day, followed by 0.1 g. thrice daily on the fifth, sixth, seventh and eighth days. (3) Pamaquin, plasmoquine base 0.01 g. twice daily and 0.1 g. mepacrin once daily from the ninth to thirteenth day inclusive. (4) A maintenance dose of mepacrin (0.1 g. daily) for four weeks, commencing on the fourteenth day of treatment.

This treatment is well tolerated, ensures effective schizonticidal action and complete destruction of gametocytes. It will cure malignant tertian malaria in the vast majority of cases, prevent the patient becoming a carrier, and

eliminate the risk of subsequent blackwater fever unless, of course, reinfection occurs. In benign tertian malaria, fever is rapidly controlled but the final results differ according to the strain of *P. vivax*, the relapse rate varying from 30 to 95 per cent. in different countries.

Sinton and others have found that for some strains of *P. vivax* a combined course of quinine (10 grains thrice daily) and pamaquin (0.01 g. plasmoquine base thrice daily) for ten consecutive days is the most effective means of curing benign tertian relapses.

Treatment of acute pernicious malaria.—In all cases of hyperinfection or in which clinical manifestations suggesting acute pernicious malaria are found, quinine bihydrochloride (grs. x) should be administered immediately intravenously, and this may be repeated in four to six hours. A total of 30 grains intravenously in the first 24 hours should not be exceeded. Oral quinine sulphate (40 grains daily) should be substituted as soon as the patient can swallow and be continued for three days; thereafter combined mepacrine-pamaquin treatment as described above should be continued. In cases in which coma persists or improvement is not noted despite intravenous quinine medication, an intramuscular injection of mepacrin hydrochloride (0.2 g.) or atebirin musonate (0.25 g.) is justified. The relative values of quinine and mepacrin in the treatment of cerebral malaria are not accurately known. Intravenous quinine therapy generally produces dramatic results, but at other times fails to save life. Intramuscular mepacrin therapy should be equally effective, but is handicapped by the fact that toxic nervous manifestations occasionally follow high dosage, especially in acute pernicious malaria.

Apart from the immediate administration of quinine by the fastest possible route, it is most necessary to prevent dehydration and to maintain an adequate blood volume by the intravenous injection of such fluids as (1) isotonic saline solution, (2) glucose 5 per cent., or (3) hypertonic saline containing calcium chloride (6 grains to the pint). These fluids may be given by continuous drip or intermittently. In cerebral malaria if the cerebrospinal fluid is under increased pressure, the withdrawal of 10 to 30 c.c. may be followed by clinical improvement. When there are algid manifestations or the blood-pressure is unduly low, quinine bihydrochloride may with benefit be given in a pint of one of the above solutions rather than the usual 10 c.c. of isotonic saline. With malarial hyperpyrexia intravenous quinine and treatment, as in the case of heat stroke, are both essential. The naked patient is placed under a fan on a wire or rush mattress, and covered with a sheet which is kept continually moist by spraying with ice-cold water. The rectal temperature is carefully noted and hydrotherapy stopped when it reaches 102° F.

Patients with latent malaria should be warned against getting wet, prolonged immersion, exposure to cold, severe fatigue, alcoholism, and high altitudes (anoxia), as these factors tend to precipitate relapse. When a patient has to have an anæsthetic or an operation or fly at high altitudes, a course of suppressive mepacrin should be instituted.

Surgical intervention is required in those cases in which there is rupture of the spleen or torsion of its pedicle.

BLACKWATER FEVER

Synonyms.—Hæmoglobinuric or Melanuric Fever; Malarial Hæmoglobinuria.

Definition.—An acute complication of malignant tertian malaria, characterised by one or more intravascular hæmolyses of considerable severity, hæmoglobinuria, fever, vomiting, jaundice, and anæmia.

Ætiology.—Blackwater fever occurs where malaria is hyperendemic; it has a somewhat patchy distribution in tropical Africa, India, South-East Europe, especially Macedonia, South America, South-East Asia, New Guinea, etc. Native populations may enjoy apparent immunity, while colonists, imported natives and occasionally even visitors develop it. Children and adults are susceptible, and males more than females. Multiple attacks are common, and once a European has suffered from the disease he is well advised not to return to highly malarious areas. The malady is most frequent in residents of one to five years' standing, but exceptionally it may supervene within three months. The latter cases are rare, and as they may be associated with hyperinfection in which 15 to 30 per cent. of the corpuscles are infected with *P. falciparum*, it is doubtful whether they should be classified as classical blackwater fever or regarded as true malaria hæmoglobinuria originating as a direct parasitic effect on the corpuscle, such as occurs in monkeys infected with *P. knowlesi*. By far the majority of cases fall into a different category, in which parasites are either scanty or present in usual numbers at the onset of the attack. They practically all give a history of chronic malaria, often associated with irregular quinine intake, the rare exceptions being examples of latent M.T. malaria.

The chief precipitating factor is the administration of quinine to a patient suffering from an ordinary attack of malaria fever. Blood examination may have revealed parasites of *P. falciparum*, while in others *P. vivax*, *P. malariae* or *P. ovale* may have been found; even so, the available evidence entirely supports the view that to develop true blackwater fever a patient must be suffering from a latent or an overt infection with *P. falciparum*. This view has been strikingly confirmed by recent experiences with troops in New Guinea where blackwater fever has been very rare; this is attributable to the fact that overt attacks of malignant tertian malaria were immediately cured by modern therapy, and regular suppressive mepacrine (0.1 g. daily) cured latent M.T. infections.

Pamaquin (plasmaquine) may also precipitate blackwater, but mepacrine (atebrin) appears to have less tendency to do so. Various theories have been put forward to explain the hæmolysis. Some have ascribed it to a biological lysin, and others suggest it may have an anaphylactic origin or be caused by direct hæmolytic action of an anti-malarial drug on the corpuscle. There is, however, no evidence of dermal hypersensitivity or of idiosyncrasy to quinine, and no lysin has been demonstrated. Prehæmolytic swelling of the corpuscle has been demonstrated in attacks of hæmoglobinuria induced experimentally by giving quinine to a patient of blackwater fever diathesis suffering from M.T. malaria; after cure quinine administration no longer produced hæmoglobinuria (Fairley and Murgatroyd). Recently Macgrath, Findlay and others have reported that (1) there is a substance in serum

which normally inhibits a lytic agent produced in the tissues, and (2) the hæmolysis of blackwater fever is caused by a reduction in the amount of this inhibitory factor in the presence of a normal concentration of lytic agent.

Pathology.—*Morbid anatomy.*—The skin is jaundiced, the blood watery, and the serum sometimes tinged with hæmoglobin, while malarial pigment may persist in the viscera although not in large amounts. The liver is enlarged and soft, the bile thick and tarry, the spleen big and its pulp almost diffuent, and the kidneys are dark, swollen and congested. Microscopically, hæmosiderin is found in the liver and spleen, in which malarial pigment may also be evident. Eosinophilic granular debris blocks many of the renal tubules, and there is toxic degeneration and desquamation of the cells of the convoluted tubules. Cloudy swelling and necrosis of liver cells, especially in the centre of the lobule, may occur, while malarial pigment may be found in Kupffer's cells.

Clinical pathology.—Malarial parasites, which are present in blood smears at the beginning of the attack, are uncommon after 24 hours, and generally not demonstrable at autopsy. The urine shows albumin, oxyhæmoglobin and urobilin in excess; methæmoglobin is generally also demonstrable. Bile is present only in the more severe cases, and ketones may also appear. The characteristic sediment consists of brown granular debris and granular casts. Red blood corpuscles are scanty or absent. The plasma contains oxyhæmoglobin, and after some hours methæmalbumin as well. There is intense hyperbilirubinæmia with an indirect van den Bergh reaction of 5 to 85 units; immediate direct reactions may be observed in severe cases with toxic changes in the liver. The blood urea is markedly raised. Renal failure probably results from several factors, including decreased glomerular filtration pressure associated with vascular failure and hypotension, local interference with the renal blood supply to the tubules due to toxic vascular spasm, toxic changes in renal epithelium, and blockage of the tubules with pigmented debris. When only a limited number of nephrons are put out of action, urea retention leads to polyuria; when a large proportion of the nephrons fail to function, oliguria or even anuria results. In the latter type of case renal acidosis may develop; this is associated with lowering of the CO_2 combining power of the plasma, a decrease in serum calcium, and an increase in the blood phosphorus (Fairley and Bromfield). Anæmia is frequently profound, and in severe cases 50 per cent. of the corpuscles may be destroyed overnight. A study of the excretion curves of urinary hæmoglobin shows that several distinct intravascular hæmolyses may occur.

Results of Hæmoglobin Disintegration.—In blackwater fever the circulating corpuscles are destroyed *in situ*, and frank hæmoglobinæmia results; hæmoglobinuria ensues whenever the concentration of the extra-corpuscular hæmoglobin exceeds the renal threshold. If the reaction of the urine be alkaline, generally red urine appears containing unchanged oxyhæmoglobin; if the reaction be acid, much of the oxyhæmoglobin is converted into methæmoglobin and later acid hæmatin, which is precipitated along with granular debris, causing a variable degree of blockage in the damaged tubules. Some of the circulating hæmoglobin is absorbed directly by the reticulo-endothelial cells, with the production of hæmosiderin and bilirubin. The resulting hyperbilirubinæmia accounts both for the hæmolytic jaundice and the pleocholia, which is responsible for the bilious vomiting and dark brown stools, while the

absorption of surplus stercobilinogen causes urobilinuria, especially in the presence of liver damage. Finally, any residual circulating hæmoglobin is split into globin and reduced hæmatin (ferrous), which is oxidised to hæmatin (ferric) and unites with serum albumin to form methæmalbumin (Fairley).

Symptoms.—No recognisable pre-blackwater fever stage exists, and the patient rightly thinks an attack of malaria is impending, for which appropriate treatment is taken. The onset, which generally occurs within 24 hours, but may be delayed for one to two weeks, is usually sudden, with chill and loin pain, but in mild cases red or black urine may be the first indication. A rise of temperature is almost invariable, rigor is common, and nausea, bilious vomiting and epigastric discomfort are characteristic. The urine, which may be reddish at first, generally becomes port-wine or porter-coloured, presenting the characteristics described. As the condition progresses, polyuria, oliguria or anuria may develop. Within a few hours yellowish discoloration of the skin and conjunctivæ is apparent. This increases in intensity as hæmoglobinuria continues, but only in the severest cases is bile found in the urine. The pulse is rapid and of low tension at first, and the blood pressure in severe cases is markedly depressed (S/D equals 80/50) at onset, though later it rises. There may be severe headache, photophobia, great restlessness, anxiety, pallor, cold extremities, and thready pulse occasioned by the rapidly developing anæmia. Hiccough and Cheyne-Stokes breathing may also develop in severe cases. As many as 2,000,000 red cells per c.mm. may be destroyed in 24 hours. The spleen and liver are generally demonstrably enlarged and tender, and may cause discomfort; the former decreases in size during the attack. Localised tenderness over the distended gall bladder may also occur and loin pain, due to renal involvement, is common. The fever at onset resembles a malarial paroxysm, is highest at first, becomes intermittent or remittent later, and generally declines in three to four days, as the vomiting subsides and the urine clears. Post-hæmoglobinuric fever may appear after hæmoglobinuria has ceased and persist well into convalescence. Hyperpyrexia may develop, especially in the late phases of the disease, while some cases show a marked tendency to hæmorrhages in the skin and the gastrointestinal tract. Hæmorrhagic rashes may even simulate the eruption of typhus fever.

Several different clinical types are encountered : (1) Mild hæmoglobinuria, especially common in children, in which blood pigment in the urine may only be found for some 4 to 24 hours. The hæmoglobinuria associated with hyperinfection in adults who have only recently acquired M.T. malaria may fall into this category. (2) Severe hæmoglobinuria, associated with the clinical features already described. These are separated into two groups : (a) the polyuric type in which renal excretion is well maintained despite evidences of nitrogenous retention; and (b) the oliguric and anuric types. Catheterisation at first shows small quantities of highly albuminous, perhaps bile-stained urine, followed later by complete suppression. Anuria may set in early, and is associated with a normal or subnormal temperature. Hepatogenous jaundice may also develop. Life may be prolonged for many days, and death may occur with renal acidosis and uræmia. Toxæmic features are common in both these types. (3) Intermittent hæmoglobinuria, in which blood pigment is present in the urine from time to time, while in the intervals it disappears entirely. In these cases the temperature may continue for

some time, post-hæmoglobinuric fever is common, and icterus and anæmia are well marked.

Complications.—Complications include anuria, post-hæmoglobinuric fever, anæmia, retinal hæmorrhages, biliary colic, pigment calculi, and cholecystitis.

Course and Prognosis.—About ten per cent. of cases relapse during the course of an attack (Ross). Convalescence may be prolonged, owing to anæmia and transient renal dysfunction, but there is no evidence that chronic nephritis results. The outlook depends to a considerable extent on the rapidity of the hæmolysis and the quantity of corpuscles destroyed. The mortality rate varies from 20 to 40 per cent., and though some cases are probably doomed from the onset, in others modern therapy favourably influences the course of the illness. Thus, in a recent series receiving large blood transfusions and alkaline medication the mortality was only 15·0 per cent. Unfavourable features include rapidly increasing jaundice, grave anæmia, severe hiccough, anuria, and hyperpyrexia.

Treatment.—**PROPHYLACTIC.**—The prophylaxis of blackwater fever is the cure of M.T. malaria. As a result of measures designed to cure M.T. infections in troops in New Guinea, the incidence of blackwater was reduced to less than 1 per 3000 cases of malaria. In malaria patients in whom there is a previous history of blackwater fever, the urine should be made alkaline and mepacrine given in preference to quinine in treatment.

CURATIVE.—In most cases of blackwater fever parasites are not plentiful and rapidly disappear from the blood, and therefore specific drug treatment can generally be postponed until convalescence. If, however, hæmoglobinuria follows intravenous quinine injections for hyperinfection, anti-malarial drug therapy should be continued and alkalies administered. In the absence of knowledge concerning the rational control of hæmolysis in blackwater fever, the therapeutic indications are to combat anæmia and heart failure on the one hand, and renal acidosis and uræmia on the other, for these are the chief causes of death. Measures directed to these ends include absolute rest in bed, fluids by different routes, administration of alkalies, and blood transfusion.

Blackwater fever patients should not be moved unless it is impossible for them to be treated where they are. Careful nursing is most important, and the patient should be kept recumbent throughout the illness. In collapsed cases with low blood pressure, early blood transfusion, warmth and elevation of the foot of the bed are advisable. The diet should consist of bland fluids, fruit juices and sweetened drinks; later, milk, fruit jellies, junket and Benger's are allowed. Copious fluids are given per os; they should contain sufficient sodium bicarbonate or potassium citrate to combat acidosis and alkaline the urine, provided this can be done without producing alkalosis. Once established, the alkaline reaction should be maintained until hæmoglobinuria has ceased, provided symptoms indicative of alkalosis, such as muscular cramps, tetany and Trousseau's sign do not supervene. Rarely alkalosis may develop while the urine is still acid in reaction; estimations of the plasma bicarbonate afford valuable data in this regard and should be carried out when practicable. Macgrath and Havard consider that if an acid urine persists after 20 grams of alkali have been given in the 24 hours no further alkali should be administered.

If vomiting proves troublesome, gastric lavage may be practised and fluids containing alkalies and glucose are given intravenously. In cases in which the urine is acid in reaction, one pint of bicarbonate of soda (150 grains to one pint) may be immediately injected intravenously. This solution should be sterilised by filtration or by adding the weighed bicarbonate to cooling boiled water, since boiling is liable to partially convert it into the toxic carbonate. Alternatively 10 c.c. of a saturated solution of sodium bicarbonate and 10 c.c. of sodium lactate (four molar) may be injected; the latter exerts a more delayed and sustained effect than does the more rapidly acting bicarbonate. Such injections may be repeated as required.

Apart from combating acidosis, it is important to prevent dehydration, assist the heart and maintain a good urinary output. For this purpose a sterile solution of five per cent. glucose should be given intravenously when required, either intermittently or by continuous drip; as much as 2000 c.c. may be administered in 24 hours when fluid is not being taken satisfactorily per os.

Blood transfusion is the best means of combating anæmia, anoxæmia and circulatory failure, and it also assists in combating renal failure by increasing glomerular filtration pressure and decreasing local renal anoxia by increasing the flow of blood richer in red blood corpuscles. Up to two pints may be given intermittently as required, or better still, a reasonable blood count can be maintained by continuous intravenous drip administration. When the hæmolysis is severe and prolonged, or when the hæmoglobinuria is of intermittent type, many pints of blood may be necessary. In the polyuric type, blood transfusion is a life-saving procedure but its effect in the anuric type is more uncertain, the renal damage often proving irreversible despite all treatment. One reason for this is that blood transfusion is not undertaken early enough, i.e. at the onset of the cardio-vascular shock which accompanies any severe intravascular hæmolysis.

In anuria hot fomentations or antiphlogistine to the loins, dry cupping, and high colonic douches with hot saline (20° F.) should be instituted. The bowels should be kept open. Diuretics like caffein citrate, or even the mercurial diuretics (Neptal and Salyrgan), injected intravenously in doses of 1 c.c., are worthy of trial. In addition to blood transfusion, intravenous fluids, such as 5 per cent. or 10 per cent. glucose, may be administered, but care has to be taken to avoid pulmonary oedema and not to water-log the patient. These and similar measures should be given a thorough trial, for though many patients with anuria die, most unexpected recoveries do occur.

Convalescence.—Once hæmolysis has ceased, marked reticulocytosis, followed by rapid blood restoration, proceeds automatically in the well-fed European; iron in adequate dosage is indicated in convalescence, and liver extract or marmite may prove necessary in peasant populations living on diets deficient in good animal protein. In all cases blood transfusions are advisable if the rate of blood regeneration is unsatisfactory.

As mepacrine appears to have less tendency to induce blackwater attacks than quinine or pamaquine, and as its prolonged use will also cure a high percentage of M.T. infections, an intensive course of this drug should be given for six days, followed by a maintenance dose of 0.1 g. daily for one month, in every case of blackwater fever.

LEISHMANIASIS

Leishmaniasis is the term applied to a group of diseases caused by parasites of the genus *Leishmania*. Some of these are general infections, others are local. Of the first, there is kala-azar due to *Leishmania donovani* (Laveran and Mesnil, 1903), and infantile or Mediterranean kala-azar, caused by *L. infantum* (Nicolle, 1908). Both morphologically and serologically they appear to be the same parasite, and there seems to be little reason for separating them. Both Mediterranean and Sudanese kala-azar, however, are much more difficult to cure than the Indian type. Oriental sore, due to *L. tropica* (Wright, 1903), and American dermal leishmaniasis, due to *L. braziliensis* (Vianna, 1911), are generally regarded as distinct species, belonging to the second group.

KALA-AZAR

Definition.—Kala-azar, or black fever, is a specific disease associated with enlargement of the spleen and liver, anæmia, great emaciation and irregular fever of long duration, caused by the protozoon *L. donovani*, present in the blood and reticulo-endothelial cell system.

Ætiology.—The disease has definite geographical limitations, being commonest in India, Assam and the Mediterranean littoral, 90 per cent. of these cases occurring in children; it is also found in China, Indo-China, the Sudan, Abyssinia, Russian Turkestan, and Mesopotamia. Natives appear more susceptible than Europeans, probably owing to different habits of life. In Assam villages the introduction of an infected case generally precedes other cases, and often it appears to be a house infection (Rogers). Children and young adults are specially liable, and males appear more susceptible than females. In the Mediterranean area very young children and dogs suffer from kala-azar, whereas in India and North China the disease occurs in older people and rarely in dogs.

The non-flagellate stage of the parasite is a small oval body, 2 to 5 μ long by 1 to 2 μ broad, containing (1) a large round laterally placed nucleus (macronucleus or trophonucleus), staining bright red with Romanowsky's stain; and (2) a kinetoplast (micronucleus, centrosome) which is usually rod-shaped, stains a deep reddish-purple and has one end pointing toward the nucleus. It can be cultivated on rabbit-blood agar (N.N.N. medium) if grown for two to three weeks at room temperature (22° to 25° C.), provided the culture material has not been contaminated (Rogers). During growth, *Leishmania* bodies develop into leptomonads measuring up to 24 μ in length, with a flagellum and centrosome at one end and a central macronucleus.

This flagellate represents the stage attained in the insect vector—i.e. some sand-fly of the genus *Phlebotomus*. If after an infective feed on blood containing *L. donovani*, the sandflies (*Phlebotomus argentipes*) are nourished on raisins and not on blood, the flagellates rapidly multiply and fill the anterior portion of the stomach, block the pharynx, and extend forward to the buccal cavity and mouth parts. Blocked sand-flies cannot ingest blood, and in an effort to do so discharge flagellates into the skin. Highly successful experimental transmission to mice, hamsters and man has recently been reported by Swaminath, Shortt and Anderson using blocked sand-flies, and

the problem of Kala-azar transmission has at last been finally solved. The chief vectors are *P. argentipes* in India, *P. perniciosus* in the Mediterranean area, and *P. chinensis* in North China. Though viable *L. donovani* may be discharged from ulcers in the intestine, naso-pharynx or bladder of a kala-azar patient, it is most unlikely that man ever becomes infected except by sand-flies.

Pathology.—Leishman-donovan bodies multiply by fission, and are found crowded together in endothelial cells of the blood vessels and lymphatics, especially those of the spleen, liver, bone marrow and skin. They are also found in the mononuclear and polymorphonuclear leucocytes in the blood. At autopsy emaciation is marked, the spleen and liver are generally enlarged, while dropsical effusions and intestinal ulceration may occur. The spleen is at first soft, pulpy and friable, and later it becomes hard and fibrous; the capsule is thickened, and perisplenitis and infarcts may also be found. The liver is firm and friable, the capsule is thickened, and fatty degeneration and a nutmeg appearance are common; cirrhosis may eventually result. The bone-marrow is generally red and soft, showing a decrease of fat. The mesenteric glands are often enlarged, presenting a central necrosis. The heart is dilated and flabby, while the enter-colon may show superficial or deep ulcerations; the latter at least are of dysenteric origin (Napier).

Symptoms.—The incubation period is probably from one to four months, but cases may occur $1\frac{1}{2}$ years after exposure. The onset may be sudden, with fever simulating malaria or typhoid, or insidious. Often in febrile cases the diagnosis is not made until relapses occur and the more classical features of the disease develop. These may be classified as follows: (1) Irregular remittent or intermittent pyrexia, which, though not necessarily high, is characteristic. Periods of apyrexia spontaneously develop, and may lead to confusion with Malta fever. A double daily rise may occur in the afternoons and evenings, but this may also be noted in other diseases and is not pathognomonic. (2) Loss of hair and deepening colour or pigmentation of the skin—hence the name black fever. (3) Anæmia, with the characteristic blood changes. (4) Rapid loss of weight and cachexia. (5) Splenomegaly, which may be the first sign or only be noted after one to two months of fever. In the early stages the spleen feels soft and doughy, but not tender; later, it hardens and may reach very large dimensions. (6) The liver is generally palpable (88 per cent.), presenting a sharp lower edge. (7) Diarrhœa. There is a good appetite associated with poor digestion, which itself may lead to intermittent diarrhœa (Napier). If blood and mucus be present, intercurrent dysentery should be suspected. (8) Other features include night sweats, persistent irritating cough, palpitation, dyspnoea, low blood pressure, i.e. below 100 mm. of mercury, œdema of the extremities, and occasionally puffiness of the face. Amenorrhœa often develops, but conception may occur with congenital transmission from the mother (Low and Cooke). The blood changes, which include anæmia, leucopenia and reduction in platelet count, are due to replacement of both the leucoblastic and erythroblastic marrow by clasmatocytic tissue. The hæmoglobin is often proportionally reduced, so that the colour index may equal 1·0; in other cases it is 0·7 or 0·8. The blood picture may show anisocytosis, poikilocytosis, polychromasia and normoblasts. The leucopenia is extreme, often

sinking to 2000 per c.mm. ; in 80 per cent. of cases it is less than 4000 per c.mm. The differential count reveals a relative increase in lymphocytes and monocytes, with a decrease in neutrophiles and eosinophiles. In some instances true agranulocytosis may develop. The coagulability of the blood may be prolonged, the calcium, blood sugar and serum albumin are reduced, and the total globulin content of the blood is raised, euglobulin increasing at the expense of the pseudo-globulin fraction.

Complications and Sequelæ.—Owing to debility and bone-marrow involvement with leucopenia, the resistance to bacterial infections is markedly decreased, and influenza, broncho-pneumonia, lobar pneumonia and tuberculosis are common causes of death ; otitis media and cancrum oris may occur, especially in children. Watery diarrhoea and intercurrent dysentery are frequent. Purpura, epistaxis, bleeding from the gums and melæna may be encountered. The sequelæ include chronic splenomegaly plus severe anæmia, and cirrhosis of the liver, sometimes associated with ascites. Jaundice frequently appears within three months of treatment and may persist for several months.

Post-kala-azar dermal leishmaniasis is being increasingly recognised. Areas of depigmentation appear about a year after antimony injections, and papillomatous nodules, in which leishmania can be found, occur the following year. A xanthoma-like condition is also described, but ulceration never occurs. Parasites are demonstrable in smears and culture, and apparently they are mainly confined to the skin, as splenic puncture generally yields negative results. The condition may also appear in persons who give no history of previous kala-azar or of treatment. When the face is affected the condition has to be differentiated from leprosy. In the Sudan, non-ulcerative papillomatosis and nodules of the skin are common in kala-azar patients.

Diagnosis is generally dependent on the demonstration of *L. donovani* in smears from lymphatic glands, sternal marrow, the liver or spleen or cultures on N.N.N. medium obtained from the peripheral blood. Parasites are less common in the peripheral blood in Mediterranean than in Indian kala-azar. Aspirated material for microscopical examination must be collected in an absolutely dry syringe. Sternal marrow is satisfactory for microscopical examination or culture ; sternal puncture is free from the danger of hæmorrhage and causes little pain. Enlarged lymphatic glands along the saphenous vein or elsewhere may be punctured with a dry hypodermic needle without a syringe, and the juice which enters the needle blown on to a slide and stained.

The formol-gel or aldehyde test of Napier is of considerable value in the diagnosis of kala-azar, especially when the result is positive and associated with a leucopænia. The test is performed by adding one drop of commercial formalin (30 per cent. formaldehyde) to 1 c.c. of clear serum, which is immediately shaken and left at room temperature. When the reaction is positive the serum immediately becomes viscid, and within one or two minutes assumes a whitish opalescent appearance and sets so that the tube can be inverted without spilling. In from 3 to 20 minutes it forms a solid opaque coagulum like the white of a hard-boiled egg. For the first three months the reaction is of doubtful value, but after this it is generally positive.

Kala-azar has to be differentiated from the febrile splenomegalies of the tropics, especially chronic malaria, undulant fever and enteric fever ; schisto-

somiasis, Banti's disease and leukaemia must also be considered, and owing to the danger of hæmorrhage in the latter disease splenic puncture should never be undertaken until blood examination has excluded it. In childhood Mediterranean kala-azar has to be differentiated from Cooley's anaemia, commonly found in Greece, von Jaksch's anaemia, and acholuric jaundice.

Course and Prognosis.—Bentley showed in the Assam epidemics, prior to the introduction of antimony, that the disease lasted one to two years in chronic cases. The mortality rate, if untreated, is about 90 per cent. Intercurrent disease, severe intestinal symptoms, and cirrhosis with ascites are of grave significance. Modern therapy generally results in recovery, provided the condition is not too advanced and intercurrent disease absent.

Treatment.—**PROPHYLACTIC.**—Segregation and treatment of the sick, and abandonment of infected houses and rebuilding at distances not less than 300 yards have been effective in India. Destruction of the sand-fly vector and of its breeding-places is indicated.

CURATIVE.—The patient is put to bed on a milk or light diet adequate in vitamins. Intercurrent disease and complications should receive appropriate treatment. Three groups of specific drugs are in use, namely, the trivalent antimony compounds, the pentavalent antimony compounds, and certain aromatic diamidines recently introduced by Yorke and Ewins. The effects of specific drug treatment are to reduce the temperature to normal, decrease the splenomegaly and hepatomegaly, increase body-weight, and restore the leucocytes to normal numbers. Cure is indicated by an absence of clinical symptoms for six months, a negative aldehyde test, an increase in serum albumin associated with a decrease in total globulin involving the γ -globulin fraction, and a permanent disappearance of parasites.

(1) *Trivalent antimony compounds.*—Antimony potassium tartrate or antimony sodium tartrate are administered intravenously, as described in the section on schistosomiasis (p. 335), the only difference being that a longer course totalling some 40 to 60 grains is required.

Antimosan has also been tried; it is less toxic than tartar emetic but almost as slow in producing cure.

(2) *Pentavalent antimony compounds.*—These are now rapidly replacing the trivalent antimony derivatives owing to their more rapid action, reduced toxicity and superior parasitocidal action. They include neostam, ureastibamine, neostibosan, and stibosan. The adult dosage of the first two is 0.1 g. initially, 0.2 g. as a second dose, and 0.25 g. for each subsequent injection. In the case of neostibosan and stibosan, an initial dose of 0.2 g., with subsequent doses of 0.3 g. is advised. Debilitated patients require small doses, while children, although tolerating proportionally larger doses than adults, should receive smaller initial doses. The length of the course varies from 10 to 15 daily injections. Toxic features include nausea, vomiting, giddiness, and more rarely diarrhoea, hepatitis and jaundice, and an anaphylaxis-like syndrome characterised by urticaria, puffiness of the face, and cardio-vascular collapse. The response of Indian and Chinese kala-azar to neostibosan is in most instances highly satisfactory, but Mediterranean kala-azar requires at least three times as much of the drug to effect a cure. Sudanese kala-azar is even more refractory, and complications, such as intractable diarrhoea, hæmorrhages, cancrum oris and lobar pneumonia, are particularly prone to develop.

(3) *Aromatic diamidines*.—The best known of these recently introduced drugs is stilbamidine (4·4 diamidine stilbene). The dosage and results vary with different types of kala-azar. In India Napier recently treated 100 cases with—2 deaths; 96 were cured, and 2 relapsed. Antimony resistant cases responded as favourable as ordinary ones. For adults the initial dose was 0·025 g. injected intravenously, followed by increasing doses of 0·05, 0·06, 0·075, 0·09–0·1 g. up to a maximum of approximately 1 mg. (0·001 g.) per lb. of body weight for both adults and children, the increase being governed by the reaction of the patient. The mean total dosage given in the ordinary case was about 0·6 g., while in resistant cases it was about 0·9 g. In Sudanese kala-azar the mortality rate of a recent series was 18 per cent. (Kirk and Sati). A much more prolonged treatment and far larger total dosage may be necessary in Sudanese as well as in infantile kala-azar of Mediterranean type. In a successfully treated child in Palestine the following dosage was given: two injections of 20 mg., seven of 30 mg., two of 35 mg., 61 of 40 mg., three of 45 mg., and 52 of 50 mg. (Total 5·7 g.). Except for two intervals of six days each, the treatment was continuous. Reactions of nitrosal type may prove troublesome following these injections; symptoms include severe headache, giddiness, flushing, low blood pressure, paræsthesias, abdominal pain, and vomiting. Adrenalin (0·25 to 0·5 c.c. of 1/1000) intramuscularly just before the intravenous injection assists in controlling troublesome reactions.

Solutions of stilbamidine and similar drugs should be freshly prepared immediately before each injection. It has been found that the unsaturated amidines lose their fluorescence, and become much more toxic and less effective therapeutically after exposure to light. A number of delayed deaths associated with acute yellow atrophy were reported following successful treatment in Sudanese kala-azar when old solutions of stilbamidine which had been exposed to light had been used.

Peripheral neuritis is another toxic complication which may persist for many months and prove serious. The aromatic diamidines are undoubtedly toxic drugs and are best reserved for cases which have proved to be antimony resistant.

AMERICAN DERMAL LEISHMANIASIS

Synonyms.—Espundia; Uta; Pian Bois; Pian Cayenne; Forest Yaws; Bosch Yaws; Bubas Braziliانا.

Definition.—An infective granuloma due to *Leishmania braziliensis*, producing cutaneous nodules and ulcers on exposed surfaces; the buccal and nasal mucous membranes may be extensively involved, and also the lymph glands and lymphatics.

Ætiology.—The disease is found in South America, in Brazil, Venezuela, British and Dutch Guiana, Bolivia, Peru and Paraguay. It is specially frequent amongst wood-cutters and people living in forests. Sand-flies are almost certainly the transmitting agent. Morphologically, *L. braziliensis* is similar to *L. tropica*, but differs in the fact that it may involve mucous membranes.

Symptoms.—The incubation period is about two months. The lesion originates as an itching papule, which may develop into a blind nodule or may ulcerate, producing fungoid granulations. In 10–20 per cent. of cases,

ulcers appear at the margins of the mouth and nose, often subsequently involving their mucous surfaces, the larynx and nasal septum. Fever, joint pains and bronchitic symptoms now appear, but many years may elapse before the patient succumbs to intercurrent disease or cachexia.

Diagnosis.—Demonstration of the parasites, either in scrapings from the spreading margin of the ulcer or by culture, completes the diagnosis. Syphilis, rodent ulcer, leprosy and tuberculosis closely resemble the destructive form of *L. braziliensis*, which, however, never involves bone.

Prognosis.—This is only dangerous to life if the mucous membranes be involved (10 to 20 per cent.). If untreated, such patients die of intercurrent disease like pneumonia.

Treatment.—This is similar to that outlined for kala-azar and oriental sore. A full course of tartar emetic, antimosan, or neostibosan should be given, and local treatment for the lips and nose instituted.

ORIENTAL SORE

Synonyms.—Aleppo Sore; Baghdad Button; Delhi Boil; Biskra Button; Ashkabad Sore; Pendeh Sore; Bouton d'Orient.

Definition.—An infective granuloma of the skin and subcutaneous tissues caused by *Leishmania tropica* producing either a "dry" type or chronic papular lesion with late ulceration, or a "moist" type of papular lesion with early ulceration.

Ætiology.—Cutaneous leishmaniasis is common in Mesopotamia, Arabia, Persia, Central Asia (Russian Turkestan), North-West Frontier of India, Asia Minor, Northern Africa, Egypt, the Sudan, Nigeria, Spain, Italy and Greece.

The "dry" type is urban in distribution, occurring in cities like Baghdad, Delhi and Lahore. Practically nothing is known regarding its reservoir hosts, though, wherever it occurs, sand-flies (*P. papatasi* and *P. sargenti*) are common. The remarkable development into virulent flagellates occurring in the mid-gut and extending forward into the proboscis after feeding them on oriental sores indicates that these insects are transmitters. The disease has also been transmitted by rubbing into the excoriated skin a saline extract of crushed *P. papatasi* sent from an endemic area. The disease is auto-inoculable, but not through the unbroken skin. It is possible that occasionally it may be transmitted by personal contact with an infected case. Dogs, cats, guinea-pigs and mice are susceptible.

The "moist" type is rural, occurring in open or desert country. In Middle Asia the endemic foci are rural settlements adjoining the desert; here desert sandflies (*P. caucasicus* and *P. papatasi*) breed exclusively in the burrows of wild rodents (gerbils), which often have sores on their ears due to *L. tropica*. It has been conclusively proved that these infected gerbils serve as reservoir hosts for cutaneous leishmaniasis of "moist" type which is transmitted to man by sand-flies breeding in the burrows of these rodents.

Pathology.—Infective granulomata are produced, sections showing atrophy of the epidermis, infiltration of the corium and its papillæ with lymphocytes, plasma cells and macrophage endothelial cells containing *L. tropica*. If the nodule ulcerates secondary bacterial infection ensues, destructive and degenerative changes predominate, and leishmania become scanty. From the histo-pathological viewpoint acute and chronic oriental

sores differ in the intensity and degree of the inflammatory process. In secondary lesions appearing later, the infiltration has a tuberculous structure, with few or no parasites, while the keloid type may show epithelial cell nests. Unlike the American form the mucous membranes are rarely involved.

Symptoms.—The incubation period for the "dry" type with late ulceration is two to six months. The lesion commences as a small red papule which gradually enlarges, softens, and becomes purplish, glazed and scaly, being surrounded by a narrow dull red zone of inflammation. This may remain as a sort of blind boil for a year or more before disappearing, or, especially if injured, it may become covered with a yellow crust and ulcerate. In three or four months, the ulcer having well-defined rounded edges and a granulation tissue base exuding thin pus. Under these circumstances there may be some enlargement of the neighbouring lymph glands (10 per cent.). The sores may be single or multiple, as many as 35 having been recorded, and are common over exposed parts, especially the hands, wrists, forearms, ears, nose, face, feet and legs. Parasites are numerous in these lesions, and the virulence to mice is low.

The "moist" form has a short incubation period of one to six weeks, and rapidly ulcerates in one to two weeks. Lymphangitis is common (70 per cent.), secondary bacterial infection frequently occurring. Parasites are scanty and the virulence for mice is high. The duration of the lesions is less than six months.

Since infection or recovery from one form does not confer immunity to the other, it is probable that the two types of lesions are dependent on infection with different strains of *L. tropica*.

Various other forms of dermal leishmaniasis due to *L. tropica* have been described. They include: (1) small firm discrete nodules occurring in the course of the lymphatics; (2) warty or papillomatous outgrowths, which may resolve or ulcerate; (3) lupus-like nodules, which may implicate the cheek; and (4) a keloid form characterised by raised, shiny soft masses of infiltrated tissue covered by pinkish skin which gradually resolve without ulceration.

Diagnosis.—This is dependent on demonstrating the parasite. If ulceration has occurred, the skin at the edge of the ulcer should be sterilised with iodine, allowed to dry, punctured with a glass pipette, and the material so obtained inoculated on to N.N.N. medium. Bacterial contamination prevents growth. Direct microscopical examination of this material often shows *L. tropica* in the endothelial cells.

Prognosis.—The condition is practically never fatal even when untreated, but under these circumstances it may last 18 months, after which the patient generally possesses an immunity.

Treatment.—**PHOPHYLACTIC.**—Sand-flies and their breeding-grounds should be eradicated.

CURATIVE.—In cases which have been secondarily infected, hot boracic fomentations or antiseptic dressings should be applied until sepsis is controlled and the crusts separate. Such forms of treatment as carbon dioxide snow, X-ray, radium, zinc ionisation and diathermy are advocated, as well as local applications of ointments containing methylene-blue, iodoform, salicylic acid, protargol or rivanol. Good results have been claimed for oriol ointment containing berberine sulphate, and dianthrone (derobin,

cignolin) paint, applied with a camel hair brush and strictly confined to the ulcer surface by covering it with paraffin wax. Russian investigators advise infiltration with 5 per cent. mepacrine injected at several points; later a 10 per cent. mepacrine ointment may be used.

Vaccines have their advocates. Tartar emetic intravenously, as given in kala-azar, is still wisely used, a total course of 20 to 30 grains being given. Neostibosan is also worthy of trial when multiple lesions are present.

TRYPANOSOMIASIS

A group of diseases caused by flagellate parasites of the genus *Trypanosoma*. In Africa, man may be infected with *T. gambiense* or *T. rhodesiense*, and in South America with *T. cruzi*. Trypanosomes also produce disease in animals, the most important being nagana affecting horses, dogs, cattle and wild game in Africa caused by *T. brucei*, which is probably identical with *T. rhodesiense*. *T. evansi* produces surra and *T. equiperdum* dourine, the latter disease, like syphilis, being transmitted during coitus.

AFRICAN TRYPANOSOMIASIS OF MAN

Synonym.—Sleeping sickness.

Definition.—This disease, transmitted by the bite of tsetse flies, is caused by *T. gambiense* (Dutton, 1902) or *T. rhodesiense* (Stephens and Fantham, 1910). After initial invasion by trypanosomes, blood infection ensues with adenitis, irregular remittent fever, rapid pulse, oedema and circinate erythematous rashes; later a meningo-encephalitis results with lethargy, mental and physical degeneration, tremors, shuffling gait, convulsions, coma and death. Mild cases, with headache and slight fever, are common.

Ætiology.—The disease is limited geographically to areas where the tsetse fly abounds and occurs in Western and Central Equatorial Africa, including the Congo, Uganda, East Africa, Rhodesia, Nyasaland, etc. Natives and whites are both affected, and children and adults of both sexes prove equally susceptible. The two species of trypanosome are indistinguishable in human blood; they possess a nucleus, a posteriorly situated blepharoplast and a flagellum. *T. rhodesiense* is identified by inoculating blood into white rats, when posterior nuclear forms develop; this so rarely occurs with *T. gambiense* that the test is one of real value in distinguishing these two trypanosomes. Furthermore, *T. gambiense* manifests an uncertain pathogenicity to laboratory animals, and is relatively insusceptible to the action of normal human serum. Glossinæ take up trypanosomes from the blood during biting; these multiply in the gut and pass forward via the proventriculus and salivary ducts to the salivary glands, where further development ensues. Glossinæ become infective in three to seven weeks and remain so for life; they bite mainly in the daytime. *T. gambiense*, the central African type, is transmitted by *G. palpalis* and *G. tachinoides*; possibly the natural reservoir of infection is game, such as the reed and bush buck, etc., encountered near lakes and rivers by which these flies live, depositing their larvæ in shady, sandy soil. *T. rhodesiense*, on the other hand, is spread

by *G. morsitans* and *G. swynnertoni* which are widely distributed independently of water. The reservoir of infection is the infected game of the area: Bruce identifies this disease with nagana and regards *T. rhodesiense* as identical with *T. brucei*. As the pathology and symptomatology produced by the two African trypanosomes are similar they may be considered together.

Pathology.—The lymph glands, which are at first swollen, congested and hæmorrhagic, later undergo degenerative changes and extensive fibrosis. Enlargement of the spleen due to lymphoid hyperplasia and proliferation of endothelial cells also occurs, while thickening of the capsule is common. In the late stages trypanosomes are demonstrable in the intercellular spaces of the brain and cord, the microscopical appearances of which resemble those of meningo-encephalitis and meningo-myelitis. Mott has stressed the resemblance to general paralysis, perivascular lymphocytic infiltrations being invariable. Neuroglial cell overgrowth is also characteristic, and diffuse glial proliferation affects both the white and grey matter in the cord: the ganglion cells show chromatolysis of their nuclei, most marked in the cerebral cortex, and endothelial proliferation in the arteries may occur.

Symptoms.—Two phases are recognised: (I.) a stage of trypanosome fever when the trypanosomes are demonstrable in the blood and gland juice; (II.) the sleeping sickness stage when the cerebro-spinal fluid contains lymphocytes, globulin and perhaps trypanosomes. The incubation period probably varies from one to three weeks, and occasionally an intense local reaction follows at the original inoculation site. In many respects trypanosomiasis resembles syphilis. (I.) *Trypanosome fever.*—This is invariably seen in Europeans, but not always in natives. Its main features are: (1) an irregular remittent or intermittent temperature low in the mornings, higher at night; apyrexial periods may occur, lasting for weeks. (2) A low tension, rapid pulse of 100 to 120 per minute, which tends to persist despite a fall in the temperature. (3) An increase in the respiratory rate to 20 or 30 per minute. (4) Patches of circinate erythema, involving mainly the trunk. (5) Localised puffiness and œdema involving the feet, legs and face: the skin may be dry and irritable. (6) Polyadenitis: enlargement of the posterior cervical glands (Winterbottom's sign) is very characteristic; the epitrochlear, axillary, supraclavicular and axillary glands may also be involved; they are soft, elastic, not tender, and do not coalesce or suppurate. (7) An enlarged spleen which is generally palpable. (8) Deep hyperæsthesia, especially over bones like the tibia and manifesting a definite latent period (Keraudel's sign). Long latent periods of several months (rarely several years) may elapse before the central nervous system becomes involved, and probably some cases undergo spontaneous cure where the virulence of the trypanosome is low. Once the stage of sleeping sickness has become definitely established, the untreated patient rarely survives for longer than a year. (II.) *Sleeping sickness.*—In the *earliest phase* the patient may complain of headache, lack of concentration, disinclination for work and insomnia, associated with loss of weight, enlargement of lymphatic glands and slight tremor of the tongue. In the *intermediate phase* the countenance becomes sad, apathetic and morose, laziness and emotional instability increase, and the patient is always dropping off to sleep, even in tropical sunlight or when eating. The speech becomes mumbled and slow, the gait shuffling, and fibrillary tremors of the tongue, lips and hands develop. The reflexes are exaggerated and Romberg's

sign is present. In the *final phase* all these symptoms become more pronounced; muscular weakness is extreme, saliva dribbles from the mouth, bed-sores and flexure-contractions may develop, the patient becomes entirely bedridden, and coma and convulsions generally terminate the picture.

The classical picture of sleeping sickness described above represents that encountered in areas where the virulence of the trypanosome is high. Recent investigation has shown that in both East and West Africa many mild cases occur in which slight toxic features, such as headache and a little fever, are the only manifestations of the disease. Furthermore, people are known to have survived who have had the disease continually for 15 years or more. Lester points out that it is the severely infected patient, often with involvement of the central nervous system, who attends hospitals and dispensaries, and this has resulted in the commoner mild clinical infections remaining unrecognised.

Complications.—Intercurrent infections like dysentery and pneumonia often cause death, and, as in syphilis, abortion and still-births are not infrequent. Keratitis, iridocyclitis, and choroiditis occur, and during treatment with tryparsamide optic atrophy has to be carefully watched for.

Diagnosis.—Irregular fevers, especially if associated with cervical adenitis, should arouse suspicion in patients who have been exposed to infection, and under such circumstances laboratory assistance is invaluable. Autoagglutination of the blood is frequently observed. Trypanosomes may be found in thin or in thick blood films, or in smears from centrifuged citrated blood. Even more satisfactory is the method of gland puncture, provided the gland juice be aspirated in a dry syringe, when 87 per cent. of cases with adenitis show trypanosomes (Broden). Inoculation of white rats or guinea-pigs with blood or emulsified excised gland is also a very valuable procedure. Lumbar puncture is essential in later cases; typically the cerebro-spinal fluid, which is often under increased pressure, shows an increase in globulin and lymphocytes, and later in medium-sized and vacuolated mononuclear cells as well. The advanced cases show counts of from 15 to 100 cells per c.mm. Trypanosomes are often difficult or impossible to demonstrate, even after centrifuging the fluid, and animal inoculation.

Prognosis.—The prognosis is very hopeful in *T. gambiense*, provided modern treatment be commenced before the central nervous system is involved: after this it is more doubtful, though many cases recover. *T. rhodesiense* is a far more virulent type of disease, and most patients succumb despite treatment. Europeans appear to recover better than natives, probably because they suffer less from intercurrent disease and are treated under better conditions.

Treatment.—**PROPHYLACTIC.**—McLean, in East Africa, discovered that a population between 10–60 per square mile proved ideal for the spread of sleeping sickness, affording maximum contact between fly and man. By concentrating the population in certain areas in Tanganyika sleeping sickness was practically eradicated. Destruction of reservoir vectors, *i.e.* big game, has not proved satisfactory. Removal of forest and bush for 15 feet around lakes and rivers is a valuable measure with *G. palpalis*, but does not affect *G. morsitans*. Personal prophylaxis is important. White clothes are advisable; shorts should not be worn, and veils and gloves used when feasible.

Where possible travelling should be done at night. Duke showed that, owing to its delayed elimination, 2 grams of germanin confers protection against either *T. gambiense* or *T. rhodesiense* for at least three months.

CURATIVE.—Several specific drugs are of proved value in trypanosomiasis:

(1) Suramin (Bayer 205, germinin), a complex organic urea compound—is injected intravenously in a dosage of 1 g. at intervals of two or three days until a total of 10 g. has been administered. It is especially useful in sterilising the blood in early cases of both *T. gambiense* and *T. nigeriense*, but tends to produce albuminuria and casts in the urine. The patient should be kept at rest in bed, and throughout treatment the protein content of the diet should be limited owing to toxic effects on the kidneys.

(2) Tryparsamide (sodium N-phenylglycineamide-*p*-arsonate) is given intravenously at weekly intervals in doses of 20–40 mg. per kilo bodyweight (1.5–3.0 g. for an adult) until a total dosage of 30 g. has been administered. Children receive relatively larger doses. Untoward symptoms are jaundice and the much dreaded optic atrophy which not infrequently supervenes; its onset may be indicated by failing vision or contraction of the fields of vision, flashes of light, ocular pain, lachrymation and photophobia. Many cases of total blindness have been recorded. The greater the changes in the cerebrospinal fluid the greater the tendency to optic nerve degeneration. Patients with damage to the optic nerve resulting from the aromatic arsenicals should receive a course of sodium thiosulphate, 10 c.c. of a 20 per cent. solution being given intravenously on alternate days. Although tryparsamide is less trypanocidal than orsanine for trypanosomes in the circulating blood, it has the advantage of acting on *T. gambiense* when the cerebral nervous system has become involved. It is not justifiable to conclude that cure has resulted until the cerebrospinal fluid has remained normal for six months, and when lumbar puncture shows it to be abnormal after treatment another course of treatment must be instituted.

(3) Orsanine (Fournau "270") is the monosodium salt of 4-acetyl-amino-2 hydroxyphenylarsonic acid and is injected intramuscularly or intravenously in a dosage of 20–35 mg. per kilogram of body-weight (up to 2 grams for an adult). Injections are given once a week for 10 to 12 weeks. It produces rapid sterilisation of the peripheral blood but a very limited effect in the meningo-encephalitic stage of the disease.

In *Gambiense* infections, Yorke advocates orsanine or suramin in early cases showing a normal cerebro-spinal fluid, while in later cases with a pathological cerebrospinal fluid a course of tryparsamide is advised after a few preliminary doses of orsanine or suramin have been injected to produce peripheral sterilisation.

In *Rhodesiense* infections, early cases should be treated with suramin. Owing to the relative resistance of this trypanosome to the aromatic arsenicals the results with tryparsamide are much less satisfactory once there is pathological cerebrospinal fluid. The best results under these circumstances are obtained by combined treatment of suramin and tryparsamide. Whatever treatment is adopted, the patient's general health must be built up in every way and intercurrent disease eliminated.

Yorke and his colleagues have introduced three promising typanocidal aromatic diamidines which are given intravenously in a dosage of 50–100 mg. daily for 8 to 12 days for adults. In early *T. gambiense* infections the curative

properties of pentamidine and propamidine equal those of tryparsamide, whether the latter is given alone or preceded by antrypol, but stilbamidine is of less value. In later cases tryparsamide is much more effective than these diamidines (Laurie). For toxic reactions, see section on Kala-azar, p. 277.

SOUTH AMERICAN TRYPANOSOMIASIS (HUMAN)

Synonyms.—Chagas' Disease; Coreotrypanosis; Schizotrypanosomiasis; Brazilian Trypanosomiasis.

Definition.—A disease occurring in parts of South America caused by the trypanosome, *Trypanosoma cruzi* (Chagas, 1909), which affects the muscles, myocardium and brain of man.

Ætiology.—The disease, which has been recorded in several states in Central and South America, affects children and adults of both sexes. *T. cruzi* is a short, broad trypanosome (20 μ long) with a central nucleus and large, ovoid, posteriorly situated kinetoplast. The disease is conveyed to man by certain reduviid bugs, of the genera *Triatoma*, *Rhodnius* and *Eratyrus*, which have imbibed trypanosomes during their meal of blood. After a developmental cycle of 6–15 days, metacyclic trypanosomes are discharged in the excreta and infect man via lesions in the skin or mucous membranes. In Brazil the chief vector is *Triatoma megista*. The trypanosomes are found in the peripheral blood only for a short time after infection, after which they assume a Leishmanial form within the cells of different organs where they undergo division, and from time to time pass back into the peripheral circulation. Probably *T. cruzi* is a natural parasite of opossums and armadillos, and man is only occasionally and accidentally infected (Strong).

Pathology.—The Leishmanial forms are found especially in the heart and voluntary muscles, also in the thyroid, supra-renals, ovaries, testicle and bone-marrow, where they multiply, causing cell destruction, cellular infiltration, hyperplasia of connective tissue and fibrosis. The central nervous system shows lesions resembling meningo-encephalo-myelitis. The spleen, liver and lymphatic glands are enlarged, and according to Chagas the thyroid is congested and perhaps goitrous.

Symptoms.—Recent work has raised considerable doubt on the validity of many of the thyroidic features (cretinism, myxœdema, etc.) associated with the chronic phases of this disease; Kraus attributes them to endemic goitre with superadded infection with *T. cruzi*. The incubation period is eight to ten days. The *acute type* occurs in infants of under one year and is characterised by fever with trypanosomes in the blood, enlargement of the spleen and lymph glands, puffiness and œdema of the face and swelling of the thyroid. A proportion of cases develop the picture of encephalo-meningitis and frequently die. The *chronic type* presents a symptomatology which up to the present has not been accurately determined. Five clinical groups have been described: (1) Pseudo-myxœdematous (PPE); (2) myxœdematous; (3) cardiac; (4) nervous; (5) chronic with subacute manifestations. Serious disturbance of heart rhythm and neurological manifestations with paralysis probably result from intracellular invasion with *T. cruzi*, but until more accurate information is available eliminating endemic goitre as an ætiological factor little can be said on this phase of the disease.

Diagnosis.—In the early acute stages this is made by finding the trypano-

somes in the peripheral blood, while occasionally puncture of the voluntary muscles may reveal the Leishmanial forms. Inoculation of guinea-pigs is sometimes successful, and a reliable complement fixation reaction has been worked out by Maehado and others, using extracts of heavily infected heart muscle or cultured trypanosomes.

Prognosis.—The prognosis in acute cases, especially where the central nervous system is involved, is grave.

Treatment.—**PROPHYLACTIC.**—Destruction of the reduviid bug vectors by chemical means, fumigation, etc., is necessary. Better houses and the use of mosquito nets are important factors in preventing infection.

CURATIVE.—No specific treatment is available, the various drugs successful in African trypanosomiasis being ineffective. If myxœda be present, thyroid extract is worthy of trial.

AMŒBIC DYSENTERY

Definition.—Amœbic dysentery results from infection of the colon with *Entamoeba histolytica* (Schaudinn, 1903), and is generally characterised by an afebrile diarrhœa, three or more voluminous stools containing brownish mucus and dark red blood usually being passed daily. Latency is a marked feature, relapses are frequent, while amœbic hepatitis and liver abscesses not infrequently supervene.

Ætiology.—This disease is mainly distributed throughout the tropics and sub-tropics, but occasionally occurs in temperate regions. Both sexes and all ages are liable, though it is less common in young children. *E. histolytica* gains access to the body in its cystic form via the mouth in drinking water or food, especially vegetables, contaminated by convalescent or contact carriers, while flies either directly or indirectly may convey the infection. The cysts pass through the stomach safely, after which the walls are dissolved by the pancreatic juice, and the encysted amœbulae escape and ultimately invade the colonic mucosa. During this stage it is the large, actively motile, tissue-invading amœbæ (20 to 30 μ in diameter), containing ingested red blood cells, which are present in faecal mucus, but later, as the lesions become quiescent and begin to heal, pre-cystic amœbæ appear in the excreta, originating superficially by binary fission from the more deeply situated tissue-invading forms. Pre-cystic amœbæ are much smaller (7 to 18 μ in diameter), less actively motile, contain no erythrocytes, and must be distinguished from *E. coli*. Different races of amœbæ give rise to cysts of different size containing one, two, or four nuclei and the characteristic chromidial bodies; they are met with in the faeces of chronic cases and carriers (*vide p.* 288).

Pathology.—After passing into the glands of the large intestine, the tissue-invading amœbæ multiply, cause toxic degeneration of the lining cells, with by-stage of the tubules and the production of slightly raised yellowish nodules (Wenyon). Simultaneously, the inter-glandular connective tissues are invaded, and a toxic, gelatinous necrosis is produced, characterised by an absence of polymorphonuclear leucocytes and occasionally by thrombosis of adjacent mesenteric venules. Small abscesses form which rupture, producing superficial ulcers with undermined edges. The

process now extends through the *muscularis mucosæ* to the submucosa, larger bottle-neck ulcers sometimes resulting which are even an inch or more in diameter, and are filled with mucoid material, cell debris and amœbæ. The brown mucus and degenerated blood so characteristic of the amœboid stool originate in such lesions. Following rupture of the primary ulcer others are similarly produced, the maximum involvement being in the cæcum, ascending and sigmoid colon, which may be considerably thickened, and the rectum. Ulceration rarely extends above the ileo-cæcal valve, and even in extensive colonic involvement the intervening mucosa does not generally appear inflamed. Frequently ulcers heal with pigmented scarring of the mucosa and thickening on the peritoneal surface, while in other instances ulceration extends to the muscular layers; adhesions may form, and more rarely sloughing and perforation may lead to a fatal peritonitis. Secondary bacterial invaders probably play a prominent rôle in the development of extensive ulcerative and gangrenous lesions of this type. Invasion of the mesenteric venules may produce so-called hepatitis (miliary amœbic abscesses), or solitary or multiple amœbic abscesses of the liver, lung, brain and spleen, the chief pathological feature of which is the presence of tissue-invading amœbæ in their non-fibrous necrotic walls.

Symptoms.—The incubation period varies from three weeks to three months. The onset is generally insidious, commencing with an afebrile diarrhoea; later, three or four bulky, fetid stools containing brown mucus and degenerate blood may be passed daily. Occasionally the onset is acute, as in bacillary dysentery, with fever, pain, griping and purging associated with the frequent evacuation of bloody, brown, mucoid stools containing *E. histolytica*; tenesmus occurs if the rectum be involved. As the condition progresses considerable weight is lost, the skin becomes dry and earthy brown, and anorexia, dyspepsia, anæmia of secondary type and a mild neutrophil leucocytosis may develop. Examination often reveals thickening and tenderness of the colon, especially of the cæcum and sigmoid. Tenderness and enlargement of the liver and abnormal physical signs at the base of the right lung should also be sought for. Sigmoidoscopy generally shows the typical amœbic lesions; in the early stages small superficial yellowish nodules and petechial hæmorrhages may be noted, while later painless yellow ulcers surrounded by zones of hyperæmia appear; scrapings reveal large tissue-invading *E. histolytica*. As a rule the intervening mucosa appears normal, but occasionally a generalised proctitis may be observed which completely clears up under emetine treatment.

Patients from the tropics may give no history of dysentery yet cysts of *E. histolytica* are found in the stools. In this group recurrent abdominal pain is sometimes complained of, and physical examination may reveal localised tenderness over the cæcum, the transverse colon or the sigmoid. Nausea, flatulence and constipation are common, and a few complain of diarrhoea. Sigmoidoscopy reveals no abnormality. Appendicitis, cholecystitis, gastric or duodenal ulcer, gastritis, or diverticulitis may be suspected; yet treatment with emetine-bismuth-iodide which results in the disappearance of cysts from the fæces is not infrequently followed by the amelioration of gastro-intestinal symptoms and under such circumstances they can with reasonable justification be regarded as of amœbic origin. Many other cyst carriers from the tropics, however, complain of no symptoms

whatever, and in the absence of a history of dysentery or recurrent diarrhoea it remains uncertain whether *E. histolytica* is living on bacteria in the lumen of the gut as a harmless commensal, or has invaded the bowel wall without, producing macroscopic lesions and clinical symptoms. Such individuals constitute a potential source of danger to the community, may develop liver abscess later and are better treated once a definite laboratory diagnosis has been made.

Complications.—Post-dysenteric adhesions, retro-colic abscess, intestinal hæmorrhage and perforation with peritonitis may result by an extension of the ulcerative process. Perforations are not infrequently multiple, and are often associated with extensive gangrene of the bowel wall. The appendix has been found involved in 7 per cent of cases. Amœbic hepatitis associated with fever, enlarged tender liver, shoulder pain and leucocytosis, and responding satisfactorily to emetine injections, is not infrequent, while liver abscess, often accompanied by rigors, sweating and involvement of the right base of the lung, may develop. If unrelieved the abscess may burst into the pleura, pericardium, stomach, or large bowel, etc., according to its anatomical situation. More rarely, amœbiasis of the brain, spleen, seminal vesicles and testicle has been recorded. Amœbic ulceration of the skin and subcutaneous tissues may develop around the sinns associated with a liver abscess, a colostomy wound or amœbic lesions involving the anus. Occasionally an amœbic granuloma may form in the rectum, closely simulating carcinoma.

Course.—The majority of cases run a chronic course, and even without specific treatment the tendency for amœbic dysentery is to improve temporarily, but relapses are frequent and very characteristic of the disease. Latency is marked, and contact carriers are frequently encountered who never suffered from dysentery.

Diagnosis.—The diagnosis is made by finding the large invading-tissue amœbæ in the fresh mucus in acute cases, and the precystic forms or cysts in the faeces of chronic cases and carriers. Four other forms of amœbic, non-pathogenic to man, occur in the faeces, namely *Entamoeba coli*, *Eudolimax nana*, *Iodamoeba bütschlii* and *Dientamoeba fragilis*; these have to be differentiated from the tissue-invading and precystic forms of *E. histolytica* in faecal examinations. Not infrequently, scrapings obtained during sigmoidoscopy reveal amœbæ despite previous negative reports on the faeces, and in any case of doubt instrumental examination should be carried out. Cytologically fewer pus cells are present in amœbic exudate than in bacillary dysentery, and Charcot-Leyden crystals also not infrequently occur. X-ray examination after a barium enema eliminates many other lesions entering into the differential diagnosis, while in distinguishing malignant disease, chronic bacillary dysentery, ulcerative colitis, bilharzial and balantidial ulcerations of the colon from chronic amœbiasis, sigmoidoscopy, reinforced by laboratory methods of examination, becomes indispensable. A complement fixation reaction has been perfected by Craig using an alcoholic extract of cultures of *E. histolytica* as antigen, but the test is not yet suited for routine diagnosis.

Prognosis.—With modern methods of treatment uncomplicated cases of amœbic dysentery almost invariably recover, and a large proportion are permanently curable. The prognosis is naturally more serious where complications like liver abscess exist, and here one or more aspirations combined

with adequate emetine therapy generally suffice, unless secondary bacterial infection has ensued. Colonic perforation with peritonitis is frequently, and brain abscess invariably, fatal.

Treatment.—**PROPHYLACTIC.**—As the disease is acquired by faecal contamination of food and water, it becomes important to ascertain that personal servants and cooks are not carriers. Food should be protected from flies, and measures should be taken to avoid contamination of water and uncooked vegetables.

CURATIVE.—Long before amœbic and bacillary dysentery were differentiated, ipecacuanha was recognised as effective in certain cases. Later, one of its alkaloids, emetine, was proved of great value by Rogers in India, and more recently other preparations, including bismuth-emetine-iodide, emetine periodide and auremetine, have been introduced. The toxic properties of emetine and its compounds should never be forgotten, and during intensive treatment it is essential that the patient be kept in bed on a simple, non-irritating, low-residue diet, milk being citrated to avoid clot formation.

Emetine is indicated where the tissue-invading amœbæ have produced visceral complications like hepatitis and amœbic abscess, and also early during the acute primary attack. Emetine hydrochloride is injected intramuscularly or subcutaneously in one grain doses daily for a period not exceeding ten days in a normal-sized adult, but the dose should be decreased in debilitated persons and those of low body weight. Children receive a dose proportional to age, for those under three years never exceeding $\frac{1}{2}$ grain, and for those under six years $\frac{1}{3}$ grain per day. Emetine is a muscle poison and, owing to the cumulative action of the drug, treatment should not be repeated within two to three weeks. Diarrhœa is commonly induced, and toxic symptoms include asthenia, cardiovascular depression, low blood pressure, tachycardia, extra systoles, extreme muscular weakness causing paresis or even paralysis of the limbs; death may occur from cardiac failure, with paroxysmal tachycardia or auricular fibrillation.

Emetine-Bismuth-Iodide (E.B.I.).—This drug is preferable to emetine hydrochloride in chronic cases and carriers showing cysts, but it has the disadvantage of causing considerable nausea and vomiting, and is best given on an empty stomach late at night in gelatine capsules, four hours after the last feed. Phenobarbitone (gr. 1) is given half an hour previously when necessary. Nightly doses, of grs. 3, are given for 10 to 12 doses, the total course varying from 30 to 36 grains. During the course patients often lose weight, and usually there is a definite fall in blood pressure and slowing of the pulse. Emetine periodide (E.P.I.), in capsules in a dosage up to grs. 6 daily, for ten days, is also effective; it tends to cause less vomiting than E.B.I.

Carbarsone, which is a pentavalent arsenical, is a reasonably effective amœbicide for both vegetative forms and cysts, and is less toxic than stovarsol, which it has largely superseded. It does not, however, cure hepatitis or amœbic abscess. The drug is administered in tablets or pulvules containing 0.25 g., one being given twice daily after food for ten days. Carbarsone can be used in ambulatory cases on a normal diet, and from these points of view possesses distinct advantages over the more toxic emetine preparations, though it is not as effective an amœbicide as E.B.I.

Chiniofon.—Chiniofon (yatren) is sodium iodooxyquinolinsulphonate, and can be given by the mouth or as a retention enema. The adult dose

is $\frac{1}{2}$ to 1 g. of the powder in gelatine capsules thrice daily for ten days, repeated if necessary after a week's interval. If given *per rectum* the bowel should be first washed out with one pint of 2 per cent. sodium bicarbonate solution to remove mucus, and an hour later 200 c.c. of a 2.5 per cent. solution of ehinifon is run into the rectum and retained for as long as eight hours if possible. Two somewhat similar preparations, vioform (40 per cent. iodine) and diodoquin (60 per cent. iodine) are widely used in America for oral treatment, but are too irritant for rectal use. Vioform N.N.R. is iodochlorhydroxy-quinoline. A total dose of 15 g. administered orally in two courses of 0.75 g. daily for ten days with a week's interval is reported to be effective in clearing the stools of *E. histolytica*.

Combined treatment.—An effective combination in chronic relapsing amoebiasis and cyst cases consists of a ten-day course of retention enemas of ehinifon in the morning and E.B.I. at night, followed by a ten-day course of carbarsone. During the latter period a liberal diet reinforced with vitamins is advisable. The results of modern therapy are as a rule satisfactory, though relapses may occur, necessitating further courses of treatment, no matter what drug is used. This has been found to be the case in troops from Burma and elsewhere suffering from amoebiasis during the present war, when considerable numbers of selected refractory cases have returned to England. In certain of these patients presenting a palpable tender colon, an enlarged liver and gross ulceration of the colon, a preliminary course of penicillin (2 million units) and sulphasuxidine (60 g.) followed by a standard course of anti-amoebic treatment has been followed by most successful results (Biggam and Drew). Temporary healing of amoebic ulcers may be sometimes observed by sigmoidoscopy to follow a course of sulphaguanidine or sulphasuxidine therapy, and it now appears probable that these drugs, and especially penicillin, can play a valuable rôle in such cases by eliminating secondary bacterial invaders and permitting a subsequent course of amoebicidal drugs to eradicate *E. histolytica* effectively.

Surgical complications.—Emetine should always be given to relieve congestion in hepatitis and also in amoebic abscess before needling (Rogers). Open operation and drainage should be confined to abscesses secondarily infected with bacteria. Amoebic appendicitis is only part of an amoebic typhlitis, and responds satisfactorily to emetine. Perforation is almost invariably fatal, even when immediately operated on.

For BACILLARY DYSENTERY, see p. 123.

CILIATE DYSENTERY

Definition.—An ulcerative condition of the colon caused by *Balantidium coli* (Malmstreñ, 1857).

Ætiology.—Human infections generally occur amongst those having occupational contact with pigs, which also harbour this ciliate; cases have been reported from Europe, America, Asia and Africa. The ciliate is egg-shaped, 50 to 80 μ long by 30 to 55 μ broad; large and smaller forms are described. At its anterior end is the peristome; its interior contains a sausage-shaped macronucleus, a micronucleus and vacuoles, while externally the whole body is covered with longitudinal rows of cilia. Encysted forms,

50 to 60 μ long, also occur in the fæces. As healthy carriers are frequently encountered, it is possible that there is some secondary bacterial or other factor which determines the pathogenicity of *Balantidium coli*.

Pathology.—The colon, and more rarely the ileum, show ulcers distinguishable from amœbic lesions only by the demonstration of *Balantidium coli*, which is found both in the cavity of the ulcer and the surrounding submucosa; it may also invade adjacent lymph glands, but not the liver.

Symptoms.—In many cases the disease remains latent and symptoms are absent. In others the onset is insidious, with loose motions, later followed by sanguineous, mucoid stools typical of chronic dysentery; anæmia may develop. Intestinal perforation has been reported, but never liver abscess.

Diagnosis.—Sigmoidoscopy may show colonic ulcers, but diagnosis is dependent on demonstrating *Balantidium coli* or its cysts in the excreta, or in scrapings from the ulcers themselves.

Prognosis.—The mortality rate including latent cases is about 7 per cent. (Walker), but in those showing active dysentery it may reach 29 per cent. (Strong).

Treatment.—Most of the remedies tried have not been satisfactory. Aguilar advises restricting carbohydrates and increasing protein and fresh vegetables. Stovarsol in doses of 0.25 g. (4 grains) twice daily after meals for one week or carbarsone in a similar dosage for ten days holds out some prospect of cure. High colonic irrigation with solutions of iodine, quinine and silver nitrate have been recommended, but owing to the spontaneous disappearance of the ciliates from time to time the value of different remedies is difficult to assess.

FLAGELLATE DIARRHŒA

There are three common intestinal flagellates of man, *Giardia intestinalis* (Lambl, 1859) which inhabits the upper intestine, *Trichomonas hominis* (Lavaine, 1860) and *Chilomastix mesnili* (Wenyon, 1910) found in the cæcum and colon. Considerable controversy has arisen regarding their pathogenicity and, though admittedly they are more common in cases of diarrhœa than in healthy individuals, nowhere do they actually invade the intestinal mucosa. Encysted flagellates are frequently found in normal stools, and Dobell has pointed out that the free flagellate forms which are naturally adapted to a fluid medium only appear when the stools become liquid or loose. From a clinical viewpoint, however, *Giardia intestinalis* has some claim to pathogenicity.

GIARDIA INTESTINALIS (Lambl. 1859)

Synonyms.—*Lambia intestinalis*; *Giardia lambia*.

Ætiology.—This parasite inhabits the jejunum and duodenum and occasionally reaches the bile ducts. It is a pear-shaped flagellate (10 to 18 μ long \times 5 to 10 μ broad), possessing a concave sucker on its ventral surface, and in the encysted form may persist for many years in the fæces.

As with certain other flagellates decreased or absent secretion of hydrochloric acid in the stomach appears to predispose to infection, and after gastrojejunostomy they may be found in aspirated gastric juice.

Pathology.—In animals the glands of the small intestine may be found packed with giardia, and though they never cause ulceration or hæmorrhage, hyperinfection may lead to surface irritation (Wenyon). It is possible that in this fashion catarrhal enteritis results.

Symptoms.—Though encysted forms are often found in the fæces in healthy individuals, periodic attacks of diarrhœa may occur associated with the passage of large quantities of clear mucus or ochre-yellow stools in which enormous numbers of free flagellates occur. The demonstration of these flagellates in the bile by means of a duodenal tube does not constitute evidence of pathological invasion of the biliary passages and gall bladder, and the present tendency to attribute all manner of symptoms to Giardia infection is to be deprecated.

Prognosis.—This is good ; fatal cases in man are unknown.

Treatment.—Mepacrine hydrochloride (atebrin) in a dosage of 0.1 g. t.d.s., p.c. for a period of five days generally eradicates Giardia infection permanently.

N. HAMILTON FAIRLEY.

F. RICKETTSIA DISEASES

INTRODUCTION

Rickettsiæ are small, non-motile, Gram-negative bodies usually less than 0.5 in diameter. They are more or less pleomorphic, and are found in both host tissues and arthropod vectors. They can only be cultivated in the yolk sac of the developing chick, and suspensions can also be obtained from the lungs of infected rats and mice. In tissue they are mainly located within mesothelial cells, either in cytoplasm or nucleus. Ricketts (1909) first noted these bodies in guinea-pigs and monkeys with Rocky Mountain spotted fever, and since then several varieties affecting man have been described. Thus, classical louse typhus is caused by *Rickettsia prowazeki*; murine or flea typhus by *R. prowazeki* var. *moscri*; Rocky Mountain exanthematic spotted fever by *Dermacentorixenus rickettsi*; tsutsugamushi disease by *R. orientalis*; trench fever by *R. quintana*; and "Q" fever by *R. burneti*.

An ever-increasing number of typhus-like fevers is being described in different parts of the world caused by rickettsiæ, and carried by arthropods like lice, fleas, ticks and mites in which rodents play an important rôle as reservoirs of infection. They have been classified on a geographical basis, according to their insect vectors, or in terms of their agglutination reaction with OX2, OX19 and OXK strains of *Bacillus proteus*.

The following modified table, published by the Army Pathology Laboratory Service (1941), summarises data regarding the Rickettsial diseases affecting man :—

DISEASE.	RICKETTSIA.	GEOGRAPHICAL DISTRIBUTION.	INSECT VECTORS.	POSSIBLE VERTEBRATE RESERVOIRS.
Exanthematic typhus.	<i>Rickettsia prowazeki</i> .	Europe, Abyssinia, North Africa, Belgian Congo, Asia Minor, Persia, North China, Mexico.	Louse <i>Pediculus humanus</i> .	Man.
Endemie or murine typhus.	<i>R. prowazeki</i> var. <i>mooseri</i> (= <i>R. muricola</i>).	Worldwide.	Rat flea <i>Xenopsylla cheopis</i> .	Rat (squirrel, shrew).
Tsutsuga-mushi disease.	<i>R. orientalis</i> (= <i>R. tsutsuga-mushi</i>).	Japan, Formosa, Malaya, Java, Sumatra, New Guinea, North Queensland.	Larva of <i>Trombicula akamushi</i> (Japan) <i>T. deliensis</i> (India). <i>T. fletcheri</i> (New Guinea)	Volc. Rat. Bandicoot.
Trench fever.	<i>R. quintana</i> (= <i>R. volhynica</i> and probably <i>R. weigli</i>).	North Africa.	Louse <i>P. humanus</i> .	Man.
Rocky Mountain spotted fever (Eastern & Western forms).	<i>Dermacentor zensus rickettsi</i> .	U.S.A.	<i>Dermacentor andersoni</i> , <i>D. variabilis</i> ,	Goats, hares and other rodents.
Fièvre boutonneuse.	<i>D. rickettsi</i> var. <i>conori</i> .	Mediterranean zone.	Dog tick. <i>Rhipicephalus sanguineus</i> .	Dog.
South African tick typhus.	<i>D. rickettsi</i> var. <i>pilgeri</i> .	South Africa. ¹	Tick. <i>Hæmaphysalis leachi</i> .	Dog ?
Sao Paulo rural typhus.	<i>D. rickettsi</i> var. <i>brasiliensis</i> .	Southern Brazil.	Tick <i>Amblyomma cajennense</i> .	Opossum.
Q fever.	<i>Rickettsia burneti</i> (= <i>R. diaporica</i>).	Australia. U.S.A.	Ticks <i>Hæmaphysalis humerosa</i> , <i>Dermacentor andersoni</i> , <i>D. occidentalis</i> , <i>Amblyomma americanum</i> <i>Rhipicephalus sanguineus</i> ?	Bandicoot.

¹ Tick-borne typhus also occurs in Abyssinia and in Kenya where the dog tick *Rhipicephalus sanguineus* acts as vector.

Rickettsiæ possess heat-labile and heat-stable antigens, and sera from typhus patients contain or may contain the two corresponding types of antibody. Though purified suspensions of rickettsiæ are now being used in agglutination and complement fixation tests for typhus, most pathologists have to rely on the agglutination test with *Proteus* OX antigens as the sole test available for routine diagnosis.

The relationship, if any, between the rickettsias and the various strains of *B. proteus* which have from time to time been isolated from typhus cases and are agglutinated in different fashions by sera derived from typhus-like patients remains undetermined.

The Weil-Felix Reaction.—Suspensions of OX19, OX2 and OXK strains of *B. proteus* are now employed in this agglutination test. Originally the reaction was carried out with living suspensions, but now the alcoholic method, which destroys the flagella and preserves solutions of "O" antigen for six months, is used. In general it may be said that OX19 is the main antigen for louse and flea-borne typhus, OXK for mite typhus, while the sera from patients with tick typhus, as a rule, react in low titre to all three strains. Felix thinks the strain forming the main antigen for the tick-borne group has yet to be discovered. The serum from patients with "Q" fever does not react with any of these strains.

For clinical purposes, a rising titre exceeding 1 in 125 may be taken as diagnostic. The test should be made as early as possible in order to estimate subsequent rises in titre. A significant rise is generally well established by the tenth day. The maximum titre of 1/1000 to 1/50,000 may not be attained until convalescence, after which the reaction weakens and gradually becomes negative.

Though the Weil-Felix reaction is of little diagnostic utility during the first week except in louse typhus, and may occasionally fail to reveal agglutinin in significant titre in severe cases until convalescence is reached, it is a reliable test of very real clinical value. Non-specific stimulation of the proteus "O" agglutinin in other bacterial infections of man rarely occurs.

FLEA TYPHUS

Synonyms.—Murine Typhus; Hone's Disease; Ship Typhus; Typhus Murin; Endemic Typhus; Urban Tropical Typhus; Shop Typhus; X19 Tropical Typhus.

Definition.—A mild typhus-like fever, with a world-wide distribution, occurring in non-epidemic form, and caused by *Rickettsia prowazeki* var. *mooseri*. It is conveyed to man by the rat flea, *Xenopsylla cheopis*, from infected rats or other rodents which are natural reservoirs of the disease.

Ætiology.—That some connection might exist between the handling of grain and rats was first suggested by Hone (1922) in South Australia. Dyer and others (1931) found that fleas collected from rats and injected into guinea-pigs produced the disease. Nicolle (1933) described the same disease under the title "Typhus murin" in sailors in French warships.

R. prowazeki var. *mooseri* has a similar morphology to *R. prowazeki*, which causes epidemic typhus, and the Weil-Felix reaction with OX19 strains is similarly positive in the two diseases. The two varieties of the disease can

be differentiated serologically only by complement fixation and agglutination tests with rickettsial antigens. They also differ in as much as *R. prowazeki* var. *mooseri* gives a positive scrotal reaction when inoculated into guinea-pigs. However, it has been found in Mexico that a strain which at first gave a negative scrotal reaction later gave a positive reaction after repeated passage through these animals. *R. prowazeki* and *R. prowazeki* var. *mooseri* may therefore be identical and epidemic typhus have a murine origin, the strain becoming ultimately modified by repeated passage through man.

Brill's disease is generally classified as murine or flea typhus, but Zinsser maintained as a result of investigations in the U.S.A. that it merely represented recrudescences of latent louse-borne typhus in Russian and other immigrants who had suffered from epidemic typhus many years previously.

Pathology.—Patients rarely die with flea-borne typhus, but there is no evidence that the lesions differ from those of mild epidemic typhus. In infected animals pathological changes are very similar to those caused by *R. prowazeki* except in the guinea-pig, where the scrotum becomes dusky red, swollen and inflamed, the tunica is thickened and may show hæmorrhage and exudate, and the testicle is swollen. This is known as the Neill-Mooser reaction, and is feeble and inconstant with *R. prowazeki*.

Symptoms.—The incubation period is generally 8 to 14 days. As a rule the onset is rapid, with chilliness or a mild rigor and moderate temperature, or it may start more gradually with irregular initial symptoms and slowly increasing fever. The fever lasts 7 to 14 days, the temperature falling by lysis. The face becomes flushed, the conjunctivæ are somewhat injected, and headache, pains in the back and cough, perhaps associated with pulmonary basal congestion, are commonly found. The rash usually appears about the fourth or fifth day, on the chest, abdomen and inner surfaces of the arms, extending later to other parts. It consists of rose red or dusky red macules, fading on pressure and, unlike classical louse typhus, petechiæ are uncommon. In dark-skinned people the rash may be so inconspicuous as to be missed altogether.

Complications are few, but broncho-pneumonia and pleurisy with effusion may occasionally supervene.

Diagnosis.—A history of association with rats, the mild nature of the illness and the strongly positive Weil-Felix reaction to OX19 strain of *B. proteus* with negative agglutination to OXK and OX2 antigens will generally enable a diagnosis to be made, especially if the disease occurs in countries where louse typhus is not endemic.

Course and Prognosis.—The disease runs a mild course, has a low case mortality rate (1 per cent. or under), and convalescence is rapidly established.

Treatment.—PROPHYLAXIS consists essentially in rat proofing, rat destruction, and the avoidance of contact with rats. Experimentally induced immunity is good against the murine strains of Rickettsia, but owing to the sporadic nature and mildness of the disease large-scale vaccination is unnecessary.

No specific curative treatment is known; the measures adopted in louse and mite typhus are applicable.

MITE TYPHUS

A number of varieties of mite typhus has been described due to the one virus, *R. orientalis* or *R. tsutsugamushi*. For many years the scrub or rural form of tropical typhus described by Fletcher in the Federated Malay States, and transmitted by *Trombicula deliensis* from infected rats, was regarded as differing from tsutsugamushi disease inasmuch as there was supposed to be an absence of a primary lesion, lymphangitis and bubo. Lewthwaite and Savor (1940) have now identified the two viruses, and shown that in rural typhus there may be either a persisting eschar or a fleeting papular lesion which often escapes recognition by its disappearance before the onset of other symptoms. The local lesion is common in the white-skinned European and rare in the dark-skinned Tamil. In Sumatra the pseudo-typhus of Deli, transmitted by *Trombicula deliensis* from infected rats, is also identical with tsutsugamushi; though the mortality is only 5 per cent. in the indigenous population, it may be as high as 40 per cent. in Europeans. Similarly, scrub typhus encountered in India, Ceylon, Burma, Indo-China, the Philippines, the Dutch East Indies, New Guinea and on the mainland of Australia in North Queensland is transmitted by larval mites, and the virus is identical with that of tsutsugamushi disease. A remarkable feature noted in New Guinea, as elsewhere, is the variable virulence of the virus, the mortality rate in different localities varying from 1 to 30 per cent. This variable virulence is probably dependent on different strains of the one virus, though the size of the infecting dose may also be a factor.

TSUTSUGAMUSHI DISEASE

Synonyms.—Japanese River Fever; Mite Typhus; Scrub Typhus; Rural or Scrub Tropical Typhus; Pseudo-Typhoid of Deli; Sumatra Mite Fever.

Definition.—An acute disease of the typhus group characterised by fever of two to three weeks' duration, a primary sore or eschar associated with local adenitis, a maculo-papular rash, generalised lymphatic glandular enlargement, deafness, and symptoms of basal pulmonary congestion. It is caused by *Rickettsia orientalis* and is transmitted from infected field mice (voles) or rats to man by the bite of certain larval mites of the genus *Trombicula*.

Tsutsugamushi disease has assumed greater importance of recent years because thousands of Allied troops fighting the Japanese have been infected in the jungles of Burma, Malaya, and the South-West Pacific.

Ætiology.—In Japan the disease occurs commonly in the summer amongst harvesters handling the hemp crop in the Island of Nippon. Here the vole, *Microtus montebelloi*, is the reservoir host. Trombiculid mites pass through four stages in their development, but it is only the larval stage which can transmit infection to man. The rodent reservoirs in Sumatra, Malaya, and New Guinea are rats, and, as in the case of voles in Japan, the red hexapod larvæ ($400 \times 200 \mu$) are found inside the ears of their rodent hosts. The larval mite needs one feed on animal tissue-fluid for its metamorphosis, and is liable to get on to people walking through the jungle, lying on infected ground, or sitting on logs. Having attached itself to the skin and fed, the engorged

larval mite drops off and passes through the nymph stage to become adult. The nymphs and adults feed exclusively on plant juices. The adults, which are only about 1 mm. long and 0.5 mm. wide, live in soil to the depth of a few inches, and presumably deposit their eggs on the ground, where a new larval generation hatches out. Larval mites live on the ground and in rotting leaves, but they may climb up a few inches on the stems of Kunai grass, etc., or even higher on to rotten logs when stimulated by the presence of man. Once the virus is acquired by a mite larva it can pass on continuously from the adult to the egg and larva, which transmits the disease at its next animal feed. Infected areas are patchy in distribution and often of small dimensions; flooded country, the sites of old human habitations or camping grounds, especially if located near streams or at the junction of grass and jungle, are liable to be dangerous. It is important to demarcate accurately any area where the disease has been acquired, so that subsequent exposure of troops or civilians to infection may be avoided. *T. akamushi* transmits in Japan, *T. deliensis* in Malaya and India, and *T. fletcheri* in New Guinea.

There is no necessary relationship between scrub itch and scrub typhus, as the species of trombiculid mite, such as *T. minor*, which produces the former may not be a vector of the latter. Some hours after being bitten by uninfected mites, hypersensitive persons develop itchy papules, which may vesicate and later become infected with pyogenic bacteria. Large numbers of these close-set lesions may be observed round the waist, or on the legs, etc. If an infected mite inoculates rickettsiæ while biting, a primary sore or eschar is liable to result, due to multiplication of these organisms *in situ*.

Pathology.—The local eschar, with inflammatory enlargement of the regional lymph glands, petechial hæmorrhages involving the serous membranes and alimentary tract, bilateral pulmonary congestion, generalised adenitis, including the tracheo-bronchial and mesenteric lymph glands, a flabby heart, with or without dilation of its cavities, and toxic spoiling of the kidneys and liver are typical findings at autopsy. The brain may show œdema, increase in the cerebro-spinal fluid, and congestion of the superficial cortical vessels. Occasionally thrombotic lesions, such as pulmonary infarction or femoral thrombosis, are encountered, but, unlike louse-borne typhus, widespread thrombosis of the peripheral blood vessels are rare, and rickettsiæ in the endothelial cells lining the blood vessels are exceedingly difficult to demonstrate. Histopathological findings include perivascular cell infiltration, extravasation of red blood corpuscle due to toxic spoiling of the endothelial cells lining the small vessels, and degenerative toxic changes in the parenchymatous cells of the spleen, liver and heart muscle.

Symptoms.—A small papule may be evident some two or three days after the attachment of the larval mite to the skin. This either subsides or may develop into a typical eschar. At the onset of the fever the eschar is a small rounded or oval sore two to four mm. in diameter, surrounded by a raised dusky aerolar three to four mm. in width. There is a firmly attached necrotic centre, which later develops into a black slough; this separates from the tenth day onwards, producing a punched-out ulcer. Healing occurs in three to four weeks, leaving a pitted scar which is occasionally pigmented. Eschars are demonstrable in about 60 per cent. of European cases; they are generally single but occasionally may be multiple, as many as six being recorded. The site of the eschar is largely determined by the type of clothing worn. With

open shirt, shorts and stockings the lesion appears on the neck or the calf at the upper margin of the stocking. When trousers and gaiters are worn the legs are rarely affected, the common site being the arms and axillæ (30 per cent.), chest and neck (20 per cent.), and the thighs and buttocks (27 per cent.) (Williams, Sinclair and Jackson).

Fever commences some 5 to 14 days after the bite (incubation period). The onset is generally sudden, with a rise in temperature (99° to 102° F.), malaise, headache, post-orbital pain, shivering, rigors, aching pains in the back and limbs, and perhaps vomiting. Occasionally there is a period with mild malaise and headache for two or three days prior to the onset of fever.

In the *typical case* a high temperature is soon established— 103° to 104° F. being usual and up to 105° F. not uncommon. A four-hourly chart often reveals marked irregularities, the temperature being remittent, intermittent, or continuous. In some, the temperature is continuous with little tendency to remittency; in others an intermittent type of temperature is common for the first 10 to 14 days, after which the temperature tends to become continuous and subsides by lysis on the fourteenth to seventeenth day. Injected conjunctivæ, a furred cracked tongue, anorexia and constipation are frequent; and diarrhoea and abdominal distension occur in a few instances. Characteristic features appearing near the end of the first week include (1) generalised enlargement of the lymphatic glands, (2) a maculo-papular eruption, (3) pulmonary features, (4) mental symptoms, and (5) transient nerve deafness. During the second and third weeks prostration and mental symptoms increase, the early euphoria being replaced by irritability, sleeplessness, delirium or apathy, and drowsiness. The cough becomes increasingly troublesome, there is considerable loss of weight, tremor may be marked, and the superficial abdominal reflexes and knee and ankle jerks are decreased or absent. The heart sounds soften and in severe cases the blood pressure tends to fall markedly, the skin assumes a dusky hue, and the tissues over the ankles and sacrum may pit on pressure; occasionally there is incontinence of fæces and urine, with increased risk of bed sores developing. The patient may die from peripheral circulatory failure or coma in the third week, or the fever may subside by lysis with drenching sweats and steady improvement. Though the febrile stage of the disease does not generally exceed three weeks, severe cases do occur where fever continues for four to six weeks; in most of these there is some complication, such as an infected pulmonary infarct. In the average case the patient is normally well in six weeks and fit to resume his ordinary vocation within three months.

In dark-skinned Asiatics the eschar is not readily demonstrable and the rash may be so inconspicuous that it passes unnoticed. Mild suffusion of the eye, associated with photophobia, fever, mild cough, headache, deafness and slight enlargement of the glands may be the only noteworthy clinical features (Lewthwaite and Savor).

In the *mild type* the onset and course of the fever are similar, but mental changes are inconspicuous, the blood pressure is well maintained, cyanosis and œdema of the feet are absent, and the pulmonary features are transient. Such patients are well at the end of three weeks and fit to work in six to eight weeks.

In the *ambulatory type* symptoms are so mild that the patient does not

feel sufficiently ill to take to bed; positive agglutination reactions are the only criterion of diagnosis in such cases.

Special Features.—The characteristic eschar has already been described, but certain other features call for more detailed description.

(1) *Adenitis.*—By the fifth day there is often slight or moderate enlargement of the lymphatic glands, which are discrete, elastic and firm. The axillary, and superficial and deep inguinal glands are commonly affected, the cervical and epitrochlear glands less frequently. The most marked enlargement is found in the regional lymph glands draining the eschar, but even here tenderness is not marked unless secondary infection has supervened.

(2) *Rash.*—Some 50 to 70 per cent. of European patients develop a maculo-papular rash, fading on pressure. Macules first appear on the chest and abdomen from the fifth to eighth day, soon become slightly raised, assuming a maculo-papular appearance, and within 48 hours may spread to the face, neck, arms, palms of the hands, trunk, thighs, legs and soles of the feet. When fully developed these maculo-papular lesions have a diameter of from 2 mm. to 1 cm. and a dull red appearance; they commence to fade within four to five days and have usually disappeared by the fourteenth day of the disease. Macules may occasionally be observed on the soft palate. Sometimes the papular element may be lacking, and the small closely packed macules then simulate the rash of dengue or measles. In fatal cases the rash occasionally becomes petechial (Williams, Sinclair and Jackson.)

Pulmonary Features.—Cough is common early in the disease, and rales and rhonchi are frequently noted. Chest pain is not uncommon. Signs in the lungs appear from the seventh day onward, but in milder infections these features are transient and do not progress as in the seriously ill, in whom dullness, diminished vesicular murmur, abundant crepitations, rales and rhonchi are audible over both lower lobes. These features are accompanied by the development of cyanosis of the lips and an increased respiratory rate to 40 or thereabouts. Mouth breathing is frequent, and there is an irritating cough, with tenacious white or blood streaked frothy, non-purulent sputum. In cases which recover these abnormal chest signs begin to disappear at the end of the third week.

Nervous System.—Mental features are common in the seriously ill patient. During the first four days the mental state is generally normal, any change noted being towards euphoria or apathy. From the sixth to tenth day ill patients show more pronounced changes. In some the initial euphoria increases, and restless irritability, toxic confusion, insomnia and delirium supervene. Others become atonic, apathetic, drowsy and stuporous. Coma not infrequently precedes death. With clinical recovery, the mental state returns to normal.

Neurological features include nerve deafness, tremor, photophobia, tinnitus, paræsthesia, hyperæsthesia, neuritic pains, depressed superficial and deep reflexes, and urinary incontinence and retention. Nerve deafness, which is a characteristic feature, is generally bilateral. It appears about the fifth day and rarely lasts longer than a week, permanent deafness being very rare. Headache and neck stiffness may be associated with increased cerebro-spinal fluid pressure.

The cerebro-spinal fluid is often normal, but may show increased lymphocytes, increased protein, and decreased chlorides. These changes are

most commonly found about the tenth day, disappear with recovery, and are not necessarily related to neurological complications.

Laboratory Findings.—The serum gives a positive agglutination to *Proteus* OXK suspensions, not to OX19 or OX2. The agglutinin commences to increase about the seventh day, reaching a maximum titre about the twentieth day. For this reason it is sound practice to examine the blood at weekly intervals, commencing during the first week and keeping some of the first serum for subsequent tests. If a rise in the agglutination titre of at least 100 per cent. is established in successive specimens, the increase in antibody content is probably significant. In cases in which only one test is done, an arbitrary minimum diagnostic titre of 1/125 can be provisionally accepted as diagnostic of an active infection; but, as Felix points out, suspensions of *Proteus* OXK are more susceptible to non-specific "normal" agglutination by sera from man than are suspensions of OX19 and OX2, and for this reason additional caution is necessary in making a diagnosis on the basis of a low titre agglutination reaction.

The leucocyte count varies within fairly large limits, and neutropænia is not uncommon. During the first nine days the count tends to be of low normal type, *i.e.* 4000 to 7000 cells per c.mm.; later it increases. The lymphocytes are on an average below 2000 per c.mm., but increase later in cases which recover; in fatal cases the count frequently remains below 2000 per c.mm. (Williams, Sinclair and Jackson.)

Anæmia is not a marked feature, and when it occurs is of ordinary secondary type. Hæmoglobin may be decreased by 2 to 3 gms. per 100 c.c., with an equivalent reduction in erythrocytes. Mild albuminuria is the rule, and in severe cases this increases and hyalo-granular casts appear.

Complications.—These include parotitis, broncho-pneumonia, pleurisy with effusion, and infarction. Infarcts may become secondarily infected and lead to lung abscess. Femoral thrombosis may develop in the second or third week, and suppuration may occur in the course of the vein. Eye complications include conjunctival hæmorrhage, retinal hæmorrhage, and rarely thrombosis of the retinal artery with amblyopia. Epistaxis and bleeding from other mucous membranes rarely occur. Other vascular accidents include subdural hæmorrhage and intra-cerebral hæmorrhage with hemiparesis. Paresis and paralysis of different types may develop; these include ulnar paralysis, nerve deafness, facial paralysis, paralysis of scapulo-humeral type, and paralysis of the phrenic nerve, with paradoxical movement of the diaphragm demonstrable by radiological examination. Cardiac complications are uncommon, but tachycardia of nervous origin may be observed in a proportion of convalescent patients. This soon disappears if no notice is taken of the condition, but if the attention of the patient be riveted on it by frequent cardiac examinations and over-anxiety on the part of the medical attendant a cardiac neurosis may result. During the present war this danger has been narrowly averted amongst the thousands of cases of scrub typhus contracted in the South-West Pacific.

Diagnosis.—This may prove difficult or impossible in the early stages of the disease unless an eschar be present. Local and generalised lymph gland enlargement, the appearance of the maculo-papular rash, and nerve deafness are of great diagnostic assistance if present. In most cases of doubt a positive Weil-Felix reaction in the second or third week of the

disease will clinch the diagnosis. The differential diagnosis is largely a matter of geography; malaria, typhoid, paratyphoid, flea-typhus, leptospirosis, dengue, measles, broncho-pneumonia, and cerebral-spinal meningitis may require differentiation in many parts of the tropics.

Prognosis.—The case mortality rate averages about 8 to 10 per cent., but varies from 1 to 50 per cent. Big variations may be seen within the same country in people of the same race in the same year. Unfavourable features are progressively increasing nervous symptoms, cyanosis, progressively rapid respiration, cedema, Cheyne-Stokes respiration, coma, and cardiac and peripheral circulatory failure. Death is generally due to overwhelming toxæmia or respiratory complications.

Cardio-vascular Features.—The pulse rate is slower than would be anticipated from the temperature during the first week; it quickens to between 90 to 120 per minute during the second week. In non-fatal cases the pulse is regular in rhythm but may be dicrotic during the second and third week. With cessation of fever the heart-rate soon returns to normal, and during convalescence significant cardiac abnormalities are rare. From the second week onwards in severe cases the blood pressure tends to fall, the daily readings being $\frac{S}{D} = \frac{75-100}{35-60}$. Fatal cases not infrequently die with peripheral cardio-vascular failure. After recovery it takes some two weeks for the blood pressure to become normal.

Treatment.—**PROPHYLACTIC.**—This consists essentially in measures designed to destroy larval mites or avoid contact with them. Infected localities, if known, should be clearly demarcated and avoided wherever possible. If it is necessary to work in mite-infested country, anti-mite fluids, such as dibutyl and dimethyl phthalate, should be applied to the clothing, and blankets should be treated with anti-mite fluids where troops have to sleep in such country. To date no effective rickettsia vaccine is available for prophylactic use in man, and vaccine prophylaxis must be regarded as being in the experimental stage.

CURATIVE.—No specific treatment is available. Expert nursing is all important, and if possible the patient is better nursed in Fowler's position. Strict rest in bed is necessary until the patient has been apyrexial for at least ten days. A fluid intake of 140 oz. daily is advisable. Eggs, milk, junket, ice-cream, fruit juices and nourishing carbohydrates are generally well taken, and vitamin B and C reinforcement of the diet is often indicated. Intravenous injections of glucose and saline are necessary in a dehydrated patient whose water intake is unsatisfactory. Sedation is important, and phenobarbitone, nembutal or morphine should be given to ensure sleep and rest when necessary. Excited, restless patients sometimes need morphine and hyoscine or rarely paraldehyde (Williams, Sinclair and Jackson). Oxygen administration may be helpful when the patient is cyanosed and shows respiratory distress. Sulphonamides are only of value when there is a purulent sputum associated with pyogenic infection. Intestinal distension, if present, is best treated by passing a rectal tube. Intercurrent malaria should be treated with atebrian and quinine.

TICK TYPHUS

Several strains of virus are probably concerned in the causation of tick-borne typhus. The reservoir hosts are rodents and dogs, and, as Megaw points out, the epidemiological and clinical features of the different tick-borne diseases have sufficient in common to justify their being dealt with together. The agglutination reaction to all the strains OX2, OX19 and OXK tends to be of low titre.

Spotted fever of the Rocky Mountains was recognised long before any other types, and includes the milder Eastern type of spotted fever and possibly the more severe Sao Paulo fever. The latter is conveyed from rats to man by the horse tick, *Amblyomma cajennense*, and has a mortality rate of 70 per cent.; it closely resembles the graver cases of Rocky Mountain spotted fever, and its virus also immunises animals against the latter disease.

Fièvre boutonneuse and the tick-bite fevers of Kenya and South Africa have much in common. Unlike Rocky Mountain spotted fever there is usually a sore at the site of the tick bite, and in experimental animals there is cross immunisation between boutonneuse and the South African virus. Fièvre boutonneuse occurs in most countries bordering on the Mediterranean, and is conveyed from dogs by the dog-tick, *Rhipicephalus sanguineus*. Clinically, it resembles the mild form of Rocky Mountain spotted fever, but the presence of a local necrotic ulcer of dark red areola, the more nodular nature of the rash, and the low mortality rate of 1 to 2 per cent. are outstanding differences. Furthermore, the virus of *boutonneuse* fever does not, as a rule, produce scrotal swelling in guinea-pigs, nor does it give cross protection against Rocky Mountain spotted fever virus.

"Q" fever, which is caused by *R. burneti*, gives rise to a mild typhus-like fever in man and inoculated guinea-pigs. In mice inoculated with human blood collected during the fever, *Rickettsiæ* are found in the spleen and suspensions obtained from mouse tissue are agglutinated in high titre by human serum from infected cases. The Weil-Felix reaction with the serum, however, is negative to all the known strains of *B. proteus*. In Australia the bandicoot is a natural reservoir of infection and infected ticks of the species, *Hæmaphysalis hurnerosa*, have recently been collected from these animals. "Q" virus has also been found in *Dermacentor andersoni* by Dyer, in Montana, where the inhabitants of certain villages acquire the disease. Guinea-pigs, injected with a vaccine which will protect against Rocky Mountain spotted fever, are not protected against "Q" fever.

ROCKY MOUNTAIN TICK TYPHUS

Synonyms.—Rocky Mountain Spotted Fever; Spotted Fever of Eastern Type.

Definition.—A non-epidemic severe typhus-like fever long recognised in the Rocky Mountains. It is generally unassociated with a local lesion or adenitis, and is transmitted to man from infected rodents by the bites of several different species of ticks including *Dermacentor andersoni*. The disease may have a high mortality.

Ætiology.—The disease primarily affects wild rodents, and, as shown by

Wilson and Chowning (1904), is conveyed to man by ticks. Larval and nymph ticks transmit the virus from rodent to rodent, but human beings are usually infected by adult ticks of the species *Dermacentor andersoni*, *D. variabilis* and *Hæmophysalis leporispalustris*. Infected ticks transmit the infection to their offspring. It is said that a single infected tick may contain 15,000 infecting doses. The causal organism, *Dermacentrozoenus rickettsi*, was described by Ricketts (1909) in the blood of guinea-pigs and monkeys infected with Rocky Mountain spotted fever. *D. rickettsi* produces a well-marked scrotal reaction in inoculated guinea-pigs, and can be demonstrated in the fluid exudate of the tunica vaginalis prior to generalised dissemination in the blood stream.

Most infections are found in people whose occupations brings them in contact with ticks. Where town dwellers are affected, dogs probably are implicated. Most cases occur in April and May in the Rocky Mountains, and in the summer in the Eastern States of the U.S.A.

Pathology.—Pathological changes include petechial hæmorrhages involving the skin and serous membrane, enlargement of the spleen and lymph glands, and degenerative changes in the kidneys, liver and heart. Proliferation of the vascular endothelium often leads to thrombosis and possible secondary gangrene. *D. rickettsi* is found within the nuclei of mesothelial cells, not in the cytoplasm as with *R. prowazeki*. Vessels of the brain as well as the viscera are affected.

Symptoms.—The incubation period is from 3 to 14 days. A local lesion at the site of the tick bite with adenitis is rare. The onset is generally sudden, with headache, lumbar and generalised pains, and sometimes sweating, rigors, anorexia, malaise and vomiting. The tongue is coated, the conjunctivæ injected, and the temperature rises rapidly to 103° or 104° F., the maximum being reached in three or four days' time. By then, in severe cases, the face is becoming dusky and a rose-red macular or papular rash appears. Later the macules turn darker, cease to fade on pressure, and may become obviously hæmorrhagic. The rash is first seen on the wrists and ankles; later, it extends to the body generally, including the palms, soles and face. The fever lasts two or three weeks, and falls by rapid lysis. Constipation, restlessness and insomnia are usual, while severe cases may show stupor, delirium, coma and convulsions. Enlargement of the spleen is common, and may be an early feature. Later, there may be jaundice and hepatomegaly, and where the central nervous system is involved altered reflexes, and Babinski's and Kernig's signs may be elicited. A leucocytosis of 15,000 to 20,000 per c.mm. is not infrequent, but leucopenia may occur; the lymphocytes are increased. Albuminuria is the rule in severe cases.

Apart from this average classical type there are abortive cases, with transient fever lasting three or four days; ambulatory cases, with scanty rash and fever lasting seven to ten days; and fulminating cases, which die with marked nervous symptoms either before the rash has appeared or with a hæmorrhagic type of eruption.

Complications and Sequelæ.—Convalescence tends to be prolonged, especially in severe cases. Bronchitis, pneumonia, femoral and other thromboses, parotitis, hæmaturia, epistaxis and mæna may complicate the picture. Iritis, nephritis, otitis media and gangrene of the fingers, toes, tonsils, prepuce and scrotum have been recorded.

Diagnosis.—The differential diagnosis includes epidemic and other forms of typhus, typhoid and the para-typhoid fevers, and cerebrospinal meningitis. Geographical considerations, the character of the rash, and the serological and other laboratory findings are of importance. Positive serological reaction may be obtained with OXK, OX2 or OX19 strains of *B. proteus*, but often reactions in significant titre are not evident until the fever is subsiding; a steadily rising titre is, of course, diagnostic.

Prognosis.—The mortality rate varies from 5 to 90 per cent. in different geographical areas. Apart from fulminating cases, the onset of profound nervous symptoms, severe cardiovascular depression and a hæmorrhagic rash indicate a severe infection and imply a correspondingly grave prognosis.

Treatment.—In endemic areas tick-proof clothing should be worn and the body carefully searched for ticks; iodine should be applied locally after their removal. A prophylactic vaccine has been prepared by Spencer and Parker in the form of a carbolised emulsion of heavily infected ticks. It gives satisfactory protection against both Rocky Mountain and Sao Paulo fevers. Medicinal treatment follows the lines outlined for louse typhus. No specific therapy is available.

N. HAMILTON FAIRLEY.

LOUSE-BORNE TYPHUS FEVER

Synonyms.—Typhus Exanthematicus; Epidemic Typhus; Fleck-typhus; Jail or Camp Fever.

Definition.—An acute and very fatal louse-borne rickettsial infection characterised by continued fever, a maculo-papular eruption and profound prostration. In favourable cases rapid defervescence occurs about the fourteenth day.

Ætiology.—The infection is conveyed by body lice, perhaps through their bites, but more probably by cutaneous inoculation of their excreta by scratching. Head lice are also believed to be possible vectors. The disease is one of a group transmitted by lice, ticks, rat fleas, and larval mites, but differs from the others in that it has a human and not an animal reservoir. Under favourable circumstances flea-borne typhus may become transmuted into the louse-borne variety. Typhus fever can also be transmitted sporadically by the rat flea, but in epidemics the body louse is the infecting agent. Most of the factors which conduce to the spread of typhus operate by their influence on the parasites by which the disease is conveyed. The lice pass directly from the sick to the healthy, or indirectly by means of garments, bedclothes and mattresses. They migrate from the dead. Lice which have fed on infected persons can, after a few days, transmit the disease and remain infective for the rest of their short lives. Their dried fæces are known to remain infective for long periods and may possibly be air-borne as dust and inhaled. Infected lice die in about eleven days, but the rat flea remains alive and infectious for several months. Crowding of the sick together in dark, ill-ventilated rooms greatly favours the possibility of infection, whilst in the presence of free ventilation very close contact is necessary before the disease is contracted.

Typhus carriers are always verminous persons. Clothes which harbour infected lice have often transmitted the disease to distant parts. Typhus is a disease of cold and temperate climates; it occurs in those months when confinement within doors and overcrowding are most likely, but paradoxically the peak of prevalence in countries where it is endemic occurs in March, April and May. In hot climates bathing, scantiness of attire, free action of the skin, and the lethal effect of high temperatures on lice are all factors which prevent its spread. But even here it may be found at high altitudes. Predisposing causes of epidemics are verminous infestation, overcrowding, mass movements of the population and, above all, starvation. Epidemics are particularly liable to occur in times of war and famine. Typhus is rare in England, but endemic foci persist in some Irish and Scottish towns. In Russia, Eastern Europe, and Asia Minor the disease is very prevalent. It is endemic in Manchuria, North Africa, Abyssinia, and the Belgian Congo. It has been recognised in Canada, New York (Brill's disease), and Mexico (where it is known as Tabardillo).

Typhus attacks persons of all ages and both sexes. The greatest mortality is in those above middle age, at 50 years it may be 50 per cent., and between 75 and 80 years, nearly 85 per cent.; attacks in the young are less severe and very much less fatal. The average mortality is 10 to 20 per cent. In populations where the disease is endemic attacks may be very mild, but when introduced into other places the type may prove excessively severe. In Brill's disease the mortality is less than 1 per cent. By some this low mortality is attributed to a previously acquired immunity. As a rule not only does louse-borne typhus protect against itself but also, it is stated, affords protection against the endemic flea-borne variety.

Pathology.—The post-mortem appearances are those common to many acute infections and are not in themselves characteristic. Hypostatic congestion of the lungs with catarrh of the air-passages is common. Softening of the spleen and extensive degeneration of the kidneys may occur. The absence of ulcerative lesions in the bowel affords a distinction from typhoid fever. Beyond occasional meningeal congestion the central nervous system appears normal to the naked eye. Zenker's degeneration of muscle may be found.

Microscopical examination reveals discrete nodules of endothelial proliferation in the small arteries of the rash, in the brain and elsewhere. These foci are surrounded by a characteristic perivascular infiltration of epithelioid cells. The lesions may initiate thromboses or by necrosis give rise to small hæmorrhages. They are known as typhus nodules.

Prime importance is attached to Rickettsia bodies (*Rickettsia prowazeki*). These are small and pleomorphic, not more than 0.3 by 0.4μ in size. They are Gram-negative and stain by Giemsa's stain. Rickettsia bodies are found sparingly in the blood on the seventh to the twelfth day of the disease, and also in infected lice and their excreta. Similar bodies occur in the typhus nodules and in the endothelial cells of the liver.

An agglutinative phenomenon, the Weil-Felix reaction, affords a valuable means of recognising the disease. The reaction is named after two observers who discovered in the urine of patients suffering from typhus an organism of the Proteus group which is agglutinated in high dilution by the serum of those infected. The strain of Proteus concerned is known as the O variety of X19, and agglutinations have been obtained with dilutions of serum up to

1 in 30,000. Reactions in controls, if occurring at all, do not take place in dilutions exceeding 1 in 50 or, at most, 1 in 100. In half the cases of typhus the reaction is found by the fifth day, and in practically all by the tenth day, after which the titre rises for about a week. There is, however, no proof that *Proteus* X19 is capable of producing typhus, nor does it confer immunity to the disease. An agglutination test with *Ricksettia* bodies has also been elaborated (Weigl reaction).

The Wassermann reaction is almost always positive in typhus if the blood is examined before the crisis, but becomes negative again in convalescence. In inoculated persons the titre of the Widal reaction for typhoid rises steadily. This is an anamnestic reaction.

Symptoms.—The incubation period is about 12 days with extremes of 5 to 21. Eight to 10 days is a common interval when the disease is experimentally produced—the greater the virulence, the shorter the incubation.

The classical onset is sudden and ingravescence much more rapid than in typhoid. Distressing headache, giddiness, shivering or rigor, and often vomiting mark the accession. Pains in the limbs and back may be severe and apathy with muscular prostration are evident from the first. The face is flushed or dusky, the conjunctivæ injected, sometimes chemotic, and the pupils contracted. Photophobia and irritability may be present and insomnia marked. The tongue is large and coated, but soon becomes dry. Appetite is lost, thirst is great, and the bowels are generally constipated. The urine is high coloured and scanty, rich in urea and uric acid, but deficient in chlorides. Albumen may appear later and the diazo-reaction is very constant. Bronchitis and slight epistaxis may occur. The spleen may be palpable, but the abdomen is *not tumid*. *Even thus early in the disease, especially in alcoholic subjects,* marked delirium, mania or stupor may be present. If the patient has not taken to his bed he usually does so by the third day of illness. The temperature may reach 104° F. by the first night; the acme, however, is generally attained on the third or fourth day. Associated with the fever is a somewhat rapid soft pulse. Marked rapidity of the respirations is also noticeable and may lead to an erroneous diagnosis of pneumonia.

The fever (Fig. 7), which during the invasive stage may show remissions, after attaining its maximum, which may be as high as 105° or 106° F., shows little or no daily variation. At the end of the first week or a day or two later a sudden remission, which is rarely lasting, may occur (pseudo-crisis); from this period, however, the fever generally shows some abatement and terminates by a sudden or somewhat gradual crisis on the thirteenth to the seventeenth day of the disease.

The rash appears on the fourth or fifth day, first on the axillary folds, about the shoulders and on the sides of the chest and the abdomen. It avoids the face, and rarely invades the temples and forehead, nor does it appear on the palate, and seldom on the palms and soles, with these exceptions it may become general all over the body. It is most profuse on the trunk, especially on the back. The three elements of which it consists are macules, papules and petechiæ. The macular elements of the rash generally appear before the papules. They are large, blotchy, dusky in tint and appear to be in the skin rather than on it, hence the descriptive term subcuticular mottling. This mottling is best seen about the shoulders and axillæ, but often extends to the back and front of the chest, the thighs and arms. The papules resemble

the rose spots of typhoid, but are often ill-defined. At first they fade on pressure; later, unlike the spots in typhoid, they may show petechiæ, becoming dull red or brown and indelible. They do not appear in successive crops. Less constant are purple petechiæ which resemble flea-bites and sometimes also purpuric patches. The latter may appear over pressure-points and terminate in gangrenous bed-sores. The purpura indicates a severe infection, the hæmorrhagic character of which may be confirmed by the occurrence of hæmatemesis, melæna or hæmaturia. Profusion of the rash in typhus is also an indication of a severe attack. In mild cases the eruption is scanty, and in children it is very evanescent. The application of a tourniquet will cause petechial hæmorrhages within the rash.

FIG. 7.—Typhus fever. Illustrating a somewhat gradual onset and abrupt termination by crisis.

A leucopenia in the early stages is followed by anæmia and leucocytosis, in which polynuclears or monocytes may predominate.

The cerebro-spinal fluid may show a slight lymphocytosis, and also give a low positive Weil-Felix reaction. The globulin is increased.

During the second week the patient in a grave infection may enter on the terminal stage of his disease. There is less complaint of headache; delirium, if present, is less violent and of a muttering rather than maniacal type. Delusions may occur. Prostration may be extreme and sleeplessness pronounced. The face is dusky, sordes accumulate on the teeth, and a curious mousy odour emanates from the body. Day by day the nervous depression increases and the patient lies helpless on his back with a tendency to sink down in the bed. The pupils are pin-hole, the eyes half open and fixed (*coma vigil*). Although deaf and unnoticing, he mutters incoherently and can be roused with some difficulty. The tongue is brown and tremulous or lies shrivelled in the floor of the mouth. Tremors of tendons

increase, and picking at the bedclothes is apt to occur. The pulse quickens and may reach 130 per minute. It is dicrotic or almost imperceptible. The heart's impulse is feeble and the first sound faint or inaudible. The blood pressure falls steadily. Acceleration of respiration is more than ever pronounced, 40 per minute not being unusual; the breathing is shallow, and hypostatic congestion of the lung bases occurs. The urine may be retained or passed into the bed, as also the feces. Uræmia may supervene. Bed-sores are apt to form rapidly. The patient may pass away in coma, or hyperpyrexia may precede death, which is apt to occur about the 11th day of illness.

In favourable cases on the fourteenth day, sometimes earlier, sometimes later, defervescence occurs. The condition rapidly improves; the temperature falls, sometimes abruptly, perhaps more frequently by a crisis which is a little more gradual. Sleep ensues and the patient awakes from his stupor with a moist tongue and skin, a clearer intellect and perhaps a slight critical diarrhoea. Inclination for food returns, but there is still extreme weakness. Some, failing to rally after the crisis, fall into a state of collapse. In less severe cases, where the typhoid state has not been pronounced, the defervescence may occur rather earlier and recovery be much more rapid; this is especially the case with children, but as a rule convalescence is prolonged.

VARIETIES.—Typhus may occur in forms which are characterised by extreme mildness or by fulminant severity. The milder types are particularly seen among the natives of localities where the disease is endemic, and in children. They may appear in the guise of an influenza-like fever with headache, lethargy and suffusion of the eyes, or as a broncho-pneumonia. Of the severe types, that known as *typhus siderans* or *blasting typhus* is the most striking. In this form death may occur within 2 or 3 days of the onset. A meningeal variety, accompanied by head retraction, ptosis, squint and other nervous symptoms, simulates meningitis, which may indeed be present. Some cases are characterised by fierce maniacal delirium. Typhus also may assume a frankly hæmorrhagic form, but this is uncommon. Relapse is almost unknown, and authentic second attacks are rare.

Complications and Sequelæ.—Bronchitis, broncho-pneumonia, or hypostatic congestion of the lungs are the outstanding complications. Rarely laryngitis occurs and may lead to necrosis of the cartilages and œdema of the glottis. True lobar pneumonia is hardly ever seen. Diarrhoea is sometimes troublesome; it may be accompanied by abdominal distension and the passage of blood. Femoral thrombosis, analogous to that of typhoid fever, is common. Septic or gangrenous infarcts may be formed in the lungs, and gangrene of the fingers, nose or pudenda may occur. Suppurative parotitis is a marked feature of the disease, and the inflamed gland may become necrotic. Gangrenous bed-sores, too, are apt to form with great rapidity and pyæmic complications may ensue. When typhus is followed by hemiplegia or other form of paralysis, a vascular lesion should be suspected. Mania, melancholia and dementia are occasional sequels but generally clear up, although they may take several months to do so. Amongst other complications may be mentioned nephritis, cystitis, orchitis and jaundice.

Diagnosis.—For the Weil-Felix reaction a reliable smooth strain of *Proteus*, OX19, is requisite. A rising agglutination titre to this organism is most significant. Results with a titre of less than 1:200 should not be accepted as positive unless the titre has risen greatly since the onset. The

agglutination may become negative in the third or fourth week of convalescence. Occasionally titres with proteus OX2 exceed those of OX19.

As compared with *typhoid*, the onset is more sudden, prostration and nervous symptoms occur earlier and are more pronounced. The aspect is drunken, the face congested, the pupils contracted and the eyes suffused. Diarrhoea and abdominal symptoms are unusual. The eruption is more profuse and more widely distributed, and the rose spots, which are paler than those of typhoid, may show petechiæ. The termination of the fever is more abrupt. Blood cultures and agglutination tests are of great value in distinguishing the two diseases. *Lobar pneumonia*, especially the apical form with meningeal symptoms, may be mistaken for typhus, but should be eliminated by careful and repeated physical examination of the lungs. The hypostatic pneumonia of typhus is bilateral and does not show frank signs of consolidation. Herpes may occur in both diseases. *Cerebro-spinal meningitis* is now easily distinguished by lumbar puncture and examination of the cerebro-spinal fluid. *Encephalitis lethargica*, with fever, headache and delirium, must be distinguished by the absence of the characteristic rash of typhus, the negative Weil-Felix reaction, and the supervention of such signs as ptosis, ophthalmoplegia, and characteristic lethargy from which the patient can be roused. The cerebro-spinal fluid may show a lymphocytosis, without globulin increase, or it may contain blood. The prodromal rashes of *small-pox* have been mistaken for typhus. They are distinguished later by appearance of the focal eruption. *Uræmia* may complicate typhus but is sometimes mistaken for it. It is distinguished by the absence of fever and rash and the condition of the urine. Difficulty occasionally arises with a fading *measles* rash, but unlike the rash of typhus this invades the face. A history of catarrhal symptoms may also be obtained in measles. The *spotted fever of the Rocky Mountains*, which is a tick typhus, closely resembles louse typhus. In hot climates and on campaigns other possible sources of error in diagnosis are louse-borne relapsing fever (epidemics of which often coincide with those of typhus), sand-fly fever, and malaria. Influenza also may lead to difficulty.

Prognosis.—The mortality, which is low in childhood and adolescence, then progressively increases (see page 305). In aged patients, recovery is the exception. Clinical indications of gravity are persistent sleeplessness, marked subsultus, violent delirium or convulsions, evidence of a hæmorrhagic tendency, a profuse petechial rash and continued high fever or hyperpyrexia. Failing circulation is shown by lividity, coldness of the extremities and hypostatic congestion of the lungs. Suppression of urine and uræmic symptoms are also of grave import. A blood urea of 90 mgm. per c.c.m. is unfavourable, and it may rise to 200 mgm. in fatal cases. Gangrenous bed-sores, extensive parotid suppuration, pyæmic symptoms and peripheral gangrene are of bad augury, as also is persistence of a leucocytosis of over 20,000. The disease is particularly deadly to alcoholics, and fat subjects.

Treatment.—**PROPHYLACTIC.**—Every effort should be made to get rid of lice. The patient should be stripped, the hair clipped short, and the body shaved and thoroughly washed before admission to a ward. As the eggs of lice hatch in about 8 days, a second disinfection at the end of 10 days is desirable. The garments of attendants should be louse-proof, and attendants should also be immune or at all events below the age of 30 years. The clothing

of those infected, and of contacts, should be sterilised and their living rooms and their contents disinfected. The use of D.D.T. (dichlor-diphenyl-trichlor-ethane) has proved effective when diluted and dusted between clothes and skin, and also for impregnating the undergarments of those exposed to infection. Cases of typhus are best treated in isolation hospitals, and when the disease is epidemic good results are obtained by forbidding movements of the populace so that susceptibles are not introduced into infected areas and infection not carried to areas hitherto immune. Injection of the blood serum of convalescents is said to be a prophylactic, but has communicated the disease.

By cultivating the virus in lice and emulsifying their mid-guts in carbolic solution Weigl produced a protective vaccine. This contains dead *Rickettsiæ*. Vaccines have since been prepared from infected mouse lung (Cox), and from infected yolk-sacs (Castaneda). Vaccines which consist of dead organisms do not appear to afford complete protection, but those containing living organisms have at times proved dangerous.

Quarantine or supervision of immediate contacts for at least 15 days is usually recommended.

CURATIVE.—This should be on the same lines as those adopted in typhoid fever. Free ventilation, tepid sponging night and morning, careful attention to the mouth and back, and the adoption of a fluid diet, consisting of milk, beef tea, fruit juices and plenty of water, are the essentials. The bowels are usually constipated and enemas should be used. The bladder must be watched; retention of urine may lead to great restlessness and constant overflow. When the temperature rises above 103° or 104° F., tepid or cold sponging should be repeated. In hot climates, exposure to heat has a very deleterious effect. For sleeplessness, paraldehyde is the most useful hypnotic, but requires to be given in large doses. Wildly delirious patients need some form of restraint, and in these cases hyoscine should be injected if other means fail. Frequent rectal salines or the administration of glucose-saline solution intravenously, subcutaneously or by drip through Ryle's stomach tube are beneficial in toxæmia and dehydration. The tendency to collapse after the crisis should be remembered, and patients carefully watched at this period. Chemotherapy and the serum of convalescents have not proved curative, but the prospect of a potent anti-rickettsial horse serum is more hopeful.

CHARLES R. BOX.

TRENCH FEVER

Synonyms.—Volhynia Fever; Meuse Fever.

Definition.—Trench fever is a specific infectious disease, probably caused by *Rickettsia quintana*, transmitted from man to man by the body louse, *P. humanus*. Clinically it is characterised by recurrent pyrexia, headache, giddiness, severe pain in the back and limbs, conjunctival congestion, sweating, leucocytosis and splenomegaly.

Ætiology.—The disease was first recognised as a specific entity during the War 1914–1918, when it appeared on the European fighting fronts, Salonika, Egypt and Mesopotamia. Approximately 800,000 cases occurred amongst Allied troops in France during four years. No outbreak of this disease has been reported during the present war. The inoculation of blood of infected

patients into volunteers was found to be capable of causing the disease (McNee, Renshaw and Brunt). It was also proved that the blood may remain infective for 200 days. Later, it was discovered that lice which had been fed on febrile patients and were subsequently kept for 5 to 12 days at 26° to 30° C. could transmit the disease to volunteers. Once infected the lice remain infected for life. Large numbers of rickettsia bodies (*R. quintana*) were demonstrated in the mid-gut of lice fed on infected people (Töpfer); they were situated only on the surface and never within epithelial cells, and failed to cause disease in experimental animals. It would appear from the available evidence that the disease is conveyed not by the bite of the infected louse but by its excreta being rubbed into skin abrasions.

Pathology.—As the disease never proved fatal no record of autopsies are available in man. Examination of the trench fever macules in skin obtained at biopsy has shown (1) hyperæmia, (2) cedema, and (3) perivascular lymphatic infiltration; unlike epidemic typhus, there was neither necrosis of the endothelial cells lining the vessels nor hyaline thrombosis.

Symptoms.—The incubation period varies from 10 to 30 days. The onset is generally sudden, with headache, giddiness, pain in the shins, back and behind the eyeballs, and a rapidly rising temperature (103° to 104° F.). Chills and sweating are common. The conjunctivæ may be congested and the general appearance of the patient during the acute stage reflects extreme pain and discomfort. He is restless and changes his position constantly in a vain effort to get relief. Frontal and retro-orbital headache is often severe and persistent; if it be retro-occipital in type it may be accompanied by stiffness of the neck. The pain in the limbs may be of a dull aching or gnawing character, or of an acute shooting or stabbing type. Such pains are felt in the bones, especially the tibiæ, last many hours and are worse at night. At first the pain is generalised, but after a few days it becomes more localised in the loins and lower limbs. It is generally symmetrical, and may vary in situation from day to day. Associated with pain there may be intense superficial tenderness—especially over the shins—so that even the weight of the bed-clothes cannot be borne.

Splenic enlargement occurs in 70 to 80 per cent. of cases. Splenomegaly may be associated with tenderness and sometimes with rigidity of the muscles in the left hypochondrium. If palpable, the edge is firm. In the early stages the spleen increases in size during febrile relapses and decreases during the afebrile periods; later, its dimensions remain more constant. Though profuse sweating is uncommon, a peculiar feature is the rapid alternations of shivering and sweating; several such attacks may occur within 24 hours. Vomiting and diarrhoea have been described but are rare; constipation is the rule. Red macules, fading on pressure and lasting from 6 to 48 hours, are frequently seen in the first few days of fever and at times during relapses. They appear in crops on the chest, abdomen and back, are at first a rose red and later a dull red colour and measure 4 to 8 mm. in diameter. Herpes labialis is not infrequent.

Unlike typhus, the mental condition remains normal. The tendon reflexes are often exaggerated, and during fever lateral nystagmus may be induced by moving the eyes. A moderate neutrophil leucocytosis precedes and accompanies the fever. The total count rarely exceeds 20,000 leucocytes per c.mm., and there is a marked left shift. Urinary symptoms include

frequency and polyuria in the post-febrile stage; the urine may contain a trace of albumin.

Widely different types of temperature chart are encountered. The total duration of fever varies from a few days to several weeks, and in most instances irregularities in the temperature chart are common. When the disease was first encountered in France short types predominated, later the disease became more severe and more prolonged pyrexia was more common. Various types include: (1) A short bout of fever lasting about three days. (2) A similar short febrile attack followed by a period of apyrexia and a febrile relapse on the sixth, seventh and eighth day. Irregular fever sometimes followed. (3) The primary fever running more or less into the relapse and producing a saddle-back type of chart. Again irregular fever might follow. (4) A definitely intermittent type of fever manifesting regular periodicity and sometimes lasting many weeks.

Complications.—In patients with prolonged pyrexia, pain and sleeplessness lead in certain instances to mental depression, neurasthenia and so-called disordered action on the heart (D.A.H.). The latter condition, which is really a cardiac neurosis, was erroneously attributed to organic disease of the heart during the last war.

Diagnosis.—During the early febrile stage trench fever may be mistaken for influenza, dengue, typhoid, paratyphoid, typhus, malaria, relapsing fever, undulant fever, rat-bite fever and leptospirosis. Laboratory investigations will help to exclude many of the above-mentioned diseases. A five- to six-day periodicity in the temperature should suggest the diagnosis.

Prognosis.—As indicated under Symptoms, the course of the disease is very variable. The mortality is practically nil.

Treatment.—Prevention consists in delousing the individual and thoroughly disinfecting the clothing. The recent introduction of D.D.T. has considerably strengthened the control of all louse-borne diseases.

No specific drugs are available, and treatment is mainly symptomatic. The patient should be put to bed as early as possible and kept there until one week after the fever has subsided. The nutrition should be maintained, aspirin and phenobarbitone given to relieve pain and insomnia, and the patient placed in as cheerful surroundings as possible. After a severe attack a period of leave proved of value in restoring mental and physical health.

N. HAMILTON FAIRLEY.

G. INFECTIOUS DISEASES OF DOUBTFUL OR UNKNOWN ÆTIOLOGY

FOURTH DISEASE

Synonym.—Filatow-Dukes Disease.

Filatow and, later, Clement Dukes described an infectious disease which they considered distinct from scarlet fever and rubella.

It is most prevalent in spring and summer. Previous attacks of scarlet

fever and of rubella afford no protection. Premonitory symptoms are absent or trivial, the first sign usually being a rosy red rash, slightly raised, which covers the whole body in a few hours. The temperature may range from normal to 103° or even 104° F. The fauces are red, the tongue clean or slightly furred, and the pulse only accelerated in proportion to the temperature. The posterior cervical, axillary and inguinal lymph glands are enlarged to the size of peas, hard and somewhat tender. The conjunctivæ are pink. Desquamation may ensue. The incubation period is between 9 and 21 days, and infectivity lasts for 2 or 3 weeks. Most authorities either reserve judgment or refuse to recognise such a disease, alleging that some of the cases are rubella and some mild scarlet fever.

INFECTIOUS ERYTHEMA

Synonyms.—Megalerythema Epidemicum ; Fifth Disease.

A mildly infectious disease of which the ætiology and mode of transmission are unknown. With slight fever, a confluent rosy eruption appears on the cheeks, avoiding the circum-oral region. The hot swelling, with its well-defined edge, may suggest erysipelas. Discrete papules spread to the forehead and neck ; on the next day they invade the trunk and limbs, mainly the latter. The extensor surfaces and the buttocks are sites of predilection. The papules by confluence form patches, which may assume annular or gyrate patterns, spreading at the periphery and fading at the centres. The eruption disappears rapidly from the face and trunk, but may persist on the limbs for a week or more, and may recur as the result of irritation in a manner suggestive of urticaria. Complications are extremely rare. The incubation period is from 6 to 14 days. There is a slight polymorphonuclear leucocytosis. In contrast with rubella, eosinophilia may occur and plasma cells are scarce.

GLANDULAR FEVER

Synonyms.—Infectious Mononucleosis ; Monocytic Angina.

Definition.—An acute infectious fever characterised by adenitis with a great increase in the mononuclear cells of the blood and the appearance of heterophile antibodies in the blood-serum. Recovery is the rule, and complications are exceptional.

Ætiology.—Glandular fever is probably a virus infection. Invasion is through the throat, the respiratory tract or possibly the bowel. Volunteers have been infected by blood transfusion and monkeys by emulsions of the swollen glands. Its prevalence is world-wide. Usually limited to small communal outbreaks, but sporadic cases are not infrequent. It chiefly attacks children and young adults, males preponderating. The incubation period may vary from 5 to 12 days. The duration of infectivity appears to be short.

Symptoms.—In children and adolescents the onset is sudden, with fever and faucial injection. Stiffness of the neck, slight dysphagia or follicular conjunctivitis may occur. The lymph glands under the upper half of the sternomastoid muscle swell rapidly (*glandular type*). By the second or third day the glands may attain a considerable size. They are discrete and scarcely tender. The skin over them is not inflamed, nor is there any surrounding

œdema. In some cases a definite membranous angina is already present or supervenes, and glandular tenderness is more pronounced (*anginose type*). Although the glandular swelling is at first unilateral, the glands on the other side of the neck may enlarge in turn, and minor or even primary swellings of the posterior cervical, axillary and inguinal groups may occur. The adenitis is often accompanied by sharp pyrexia, the fever being irregular, and ranging from 100° to 103° F., or even higher. Exceptionally a fleeting erythematous or rubelliform rash appears on the trunk.

The adenitis of glandular fever may not be limited to superficial glands or even commence in them. Paroxysmal cough, dysphagia and, rarely, even pulmonary collapse may indicate mediastinal involvement. Vomiting and abdominal pain may accompany palpable swelling of the mesenteric glands. Appendicitis may be simulated. Slight enlargement of the spleen and of the liver is common. Rarely hepatitis and jaundice develops after a week or longer; it may even, on the evidence of the blood-count and the Paul-Bunnell test, be the only evidence of the infection. In some cases meningismus or even a mild lymphocytic meningitis has been observed.

The blood changes are diagnostic but may be very transient or delayed. After a fleeting polymorphonuclear leucocytosis or, rarely, a neutropenia, the count shows a characteristic increase in the numbers of the mononuclear non-granular cells. These may form 40 to 90 per cent. of the total leucocytes instead of the normal 20 per cent. The cells are not of uniform type, as in acute leukæmias. Aberrant cells, which in some respects resemble large primitive lymphocytes, and in some monocytes, or plasma cells, may preponderate. The total leucocyte count is rarely more than 12,000 to 18,000, but may be 30,000 or more. The red cell count is not diminished.

Heterophile antibodies, which agglutinate the red corpuscles of sheep, appear in the blood serum. This constitutes the Paul-Bunnell reaction. It becomes positive with the appearance of the swollen glands. A titre of 1 in 100, or possibly less, is diagnostic of glandular fever. Appearing about the fifth day, it may persist for 1 to 4 weeks. Sometimes its appearance is delayed and repetition of the test is necessary. These diagnostic antibodies are absorbed by ox red cells but not by guinea-pig kidney. A similar reaction which may occur after the injection of horse serum is distinguished by absorption tests. Bartlett's test, positive in a titre of 1 in 40, combines absorption and agglutination procedures. The lymphadenitis is characterised by vascular congestion and by hyperplasia of the reticulo-endothelium and germ-centres which may be packed with cells like those in the blood. Similar cells occur in the bone-marrow.

The febrile stage of the disease may last for 10 days or a month, and exacerbations of fever, with involvement of fresh glandular groups, may occur. The glandular swellings subside more slowly than the fever. A sub-acute or relapsing type with sweats and irregular pyrexia, simulating Hodgkin's disease, has been described. The mononucleosis may be very transitory, or may persist for some time. Convalescence is slow.

In some cases, mostly adult, glandular fever may differ considerably from the disease as described above. There is a febrile course, very suggestive of typhoid infection, with malaise, muscular pains, headache and perhaps epistaxis, but no marked soreness of the throat. Shivering, or even rigor, may occur. Towards the end of the first or second week of fever, a scanty

eruption of macules or papules, like those of typhoid fever, may appear on the trunk and perhaps the limbs. The diagnosis is established when glandular enlargement, usually less pronounced in this type, supervenes in the third week or later, and the fever assumes a remittent form. At this stage a relative or absolute mononucleosis is most likely to be discovered, and may be evanescent or very protracted. A membranous faucial inflammation may possibly also now be found. The spleen may enlarge. Relapses may occur, and the fever has been known to persist for many months. In some cases the Wassermann, or Kahn, reaction becomes temporarily positive. A misleading agglutination with typhoid "O" antigen in low titres may occur. Very rarely petechial eruptions accompany the fever, and the bleeding-time is increased.

A striking feature of outbreaks of glandular fever is the coexistence of infections without overt clinical signs, the blood picture being typical and the Paul-Bunnell test positive.

Complications.—There may occur a slight temporary albuminuria, with a few tube casts, but in some 6 per cent. of the cases a benign hæmorrhagic nephritis ensues. Suppurative otitis and retropharyngeal abscess have been recorded. Suppuration of the glands is rare. Serous or lymphocytic meningitis is exceptional, as are cerebral palsies and lesions of peripheral nerves.

Diagnosis.—The clinical course is so characteristic and the cervical adenitis so disproportionate to the faucial inflammation that suspicion of glandular fever should be aroused, throat swabs examined, blood counts made, and the Paul-Bunnell test applied. In the febrile form, fevers of the enteric group can be excluded by the usual bacteriological and serological tests. In the membranous form, diphtheria is excluded by absence of the Klebs-Loeffler bacillus and of acute toxæmic symptoms, despite persistent membrane. Resemblance to rubella is sometimes close, but there are differences in the blood films, and the Paul-Bunnell test will decide. Sore throat, adenitis and a maculo-papular rash may also suggest secondary syphilis, and the possibility of a positive Wassermann reaction causes further confusion. The paroxysmal cough and leucocytosis may simulate whooping cough but the Bordet-Gengou bacillus is absent, and the Paul-Bunnell test positive. Swelling of the salivary glands and even Mikulicz's syndrome have been reported in rare instances. In such cases, if authentic, mumps may be simulated. Vincent's angina may complicate glandular fever, but the occurrence of Vincent's organisms is now regarded as fortuitous. Acute leukæmia at its onset constitutes a very real difficulty, but the leucocytosis is usually far in excess of that of glandular fever and the cell type more uniform; the red cells show anisocytosis and are often nucleated. Anæmia is progressive, and the issue fatal. Hodgkin's disease is a much more chronic and progressive affection, here lymphocytosis rarely occurs; biopsy of a gland is the most certain diagnostic criterion. Tuberculous adenitis has a greater chronicity; periadenitis with suppuration and other signs of tuberculosis may be present. Septic adenitis induces a polymorphonuclear leucocytosis, and may suppurate. Agranulocytic angina is characterised by a low leucocyte count and the disappearance of all granular cells. The differentiation of glandular fever with abdominal symptoms from appendicitis and from infection jaundice is based on possible enlargement of glands, the blood picture, and the Paul-Bunnell test.

Treatment.—This is symptomatic. Ultra-violet radiation is said to hasten resolution of the adenitis. In protracted cases, injection of the blood serum of a convalescent may bring the disease to a termination. Good results are also claimed from injection of sulphanilamide. Excision of glands is unnecessary and should be avoided. Isolation for 7 days after the subsidence of the fever and glandular swellings is deemed sufficient in the acute cases.

CHARLES R. BOX.

RHEUMATIC¹ FEVER

Definition.—An acute, specific disease, characterised by fever, arthritis and a special tendency to carditis.

Ætiology and Pathology.—The essential cause of the disease is unknown. That the *materies morbi* is microbic there can be very little doubt, and for these reasons: the clinical features of the disease bear a strong resemblance to those seen in diseases of undoubted microbic origin, and especially in septicæmia due to streptococci and to staphylococci; the curves of incidence of the disease rise and fall with the curves of incidence of scarlet fever and of erysipelas; and the disease, if not interrupted by treatment, runs a natural course.

The essential causative factors of the disease have formed matter for discussion over a long period and are still by no means settled. At present three hypotheses are prevalent.

(i) *That the disease is a streptococcal infection.*—The close association with scarlet fever and with tonsillitis, diseases having strong affinities with streptococci, gives support to this view. But the difficulties in its acceptance are numerous: blood cultures are almost uniformly negative, even at the height of severe cases; cocci are not demonstrated in what is regarded as the essential histological lesion of the disease, the Aschoff node; the joint lesions, however severe, never suppurate; it has so far not been possible to incriminate any special variety of streptococcus as being specific.

(ii) *That the disease is due to a virus.*—As to this, though the view harmonises in many ways with the known facts, there are no data giving positive support to it.

(iii) *That the disease is a state of allergy.*—Those who hold this view conceive a focus of streptococcal infection, usually in the tonsil, which gives rise to a general hypersensitiveness of the body, and that this state, given certain conditions not yet defined, manifests itself by the syndrome which we call acute rheumatism. This hypothesis is thought by those who support it to explain the diversity of cocci associated with the disease. But, as Dible points out, that hypersensitivity should arise from infection by a multiplicity of strains of streptococci, rather than from one particular strain, constitutes the main difficulty in accepting this theory. Other difficulties are found in explaining why this particular form of sensitivity should be

¹ The word "rheumatic" is used throughout this article to signify conditions strictly belonging, or allied, to rheumatic fever, and not to include any of the many states loosely described as "rheumatism."

confined to streptococci, and why so small a section of the community should be affected. In no known state of allergy is there a specific histological lesion, nor is there a tendency to endocarditis.

Although rheumatic fever is probably not a contagious disease, an epidemic of sore throats, or of scarlet fever, is prone to produce a crop of rheumatic cases.

The disease is more common in humid and temperate *climates* than in others; it is probably more common in Great Britain than anywhere else. It is an urban, rather than a rural disease. The home environment is important as a contributory causative factor: bad general hygienic conditions predispose to it. The *sexes* are affected almost equally, but there is a slight preponderance in males, no doubt owing to their greater tendency to exposure. Rheumatic fever is pre-eminently a disease of pubescents and young adults, but it occurs at all *ages*, though it is uncommon in infants and in the elderly. If a person has had recurring attacks up to the age of 40, he is prone to them afterwards, but otherwise the susceptibility to the disease becomes greatly diminished after the age of 30. It is one of the striking facts of medicine that there are rheumatic families, in whom the tendency to the disease is highly marked. A certain *complexion* is common in them: a clear skin, with fair—often rufous—colouring.

Exposure, fatigue and damp are precipitating causes of the attack: a railway journey in wet clothes after muscular exercise, or sleeping in a damp bed, is a not unusual event in the patient's history of the onset. But it is equally true that many attacks come on in the absence of all these factors; indeed, attacks are not at all infrequent in hot weather. *Autumn* provides more attacks than any other season of the year.

HISTOLOGICAL MORBID ANATOMY.—A small cellular nodule, which is demonstrable in many cases of the disease, is thought by a number of observers to be specific. It is usually fusiform in shape, and consists of a fibrous matrix with many small round cells and some large cells, most of which are mononuclear. Later, this nodule becomes entirely replaced by fibrous tissue. Wherever this lesion is found, whether in the connective tissue of the heart muscle, in the synovial membranes or in the subcutaneous tissues—allowing for differences in the texture of the tissues themselves—these histological features are essentially the same. In the myocardium this lesion is easily recognisable ("Aschoff's node").

Symptoms.—In adults the onset is usually abrupt, with the sense of chill, accompanied almost at once by pains in the joints, the knees and ankles being the commonest. One or two joints usually precede the rest in order of invasion, to be quickly followed by others: wrists, shoulders, hips, neck, tarsus, metatarso- and metacarpo-phalangeal joints. Some degree of sore throat is very common, and may be a marked feature; when this is so, the tonsils usually show the redness and swelling more than other parts. By the end of the second or third day it is usual to find a considerable number of joints affected, so that the patient is already in much pain and great discomfort. The affected joints are swollen and red, and synovial effusions appear, especially in the knees, wrists and ankles. There is great variation in the extent and in the degree of the joint involvement in different cases. In a few instances less common joints share the inflammation: sterno-clavicular, vertebral, interphalangeal. The *fibrous tissues* suffer as well as the joints,

and it is often apparent that this accounts for some, at least, of the stiffness and grave discomfort. The joint effusions never suppurate.

The *temperature* usually rises to 102° to 103° F. with the arthritis and synovial effusions, and the fever remits, or even intermits, so that the chart shows an "irregular" curve. The pyrexia is peculiarly sensitive both to exacerbations in the disease (which are common), to relapses (which are also common) and to complications. Sweating is generally profuse, the sweat being of a peculiar "acid" smell. The *urine* is scanty and high coloured, and if the fever is marked there is usually a trace of albumin present; a deposit of urates, coloured brick-red by uro-erythrin, is a feature in most severe cases. As in most acute fevers, the *secretions* of the mouth and alimentary tract are lessened, leading to a heavily coated tongue, anorexia and constipation.

The *heart* is generally—some authorities believe always—affected, though the nature and the degree of the affection is variable. There are few, if any, cases in which careful examination from day to day does not reveal a slight degree of "softness" of the first sound of the heart, due, no doubt, to affection of the myocardium. The *pulse* is raised moderately in frequency (90 to 120), its volume is good but its tension is reduced. In more cases than not, probably, a soft systolic apex-bruit appears, not, however, necessarily indicating the occurrence of endocarditis. In about half of all cases there are reasons for concluding that *acute endocarditis* is present, as judged by the character of this bruit, its transmission towards the axilla, some evidence of enlargement of the heart and a rise in the temperature coincident with the appearance of the heart signs. This complication usually arises about the eighth to the tenth day.

The *blood* shows a considerable leucocytosis (15,000 to 30,000) and an acute "secondary" anemia which is a constant feature of the disease and quickly reveals itself in the patient's facies. The erythrocyte sedimentation rate is increased during the active stages of the disease.

ABERRANT TYPES.—*Subacute* attacks are common, especially in children (see p. 320) and in old rheumatic subjects. Their importance lies in the fact that all the time the heart may be suffering damage. Although this is less common in adults than in children, arthritic signs may be absent in cases of rheumatic endocarditis, as in rheumatic pericarditis.

Complications.—As already stated, about one-half of all cases develop some *heart* lesion. We have spoken of *myocarditis* and of *acute endocarditis*, and of the advent of the latter, should it arrive, about the end of the first week. The endocarditis is generally a valvulitis; most often mitral, less often aortic, but in some cases both mitral and aortic. *Pericarditis* is less common, though it may be the only manifestation of rheumatic infection; and pericardial effusion, especially of the massive sort, is nowadays quite uncommon. (For full accounts of these important cardiac complications, see special sections.)

Skin eruptions, though a specific feature of the infection, are not very common, except in children. The profuse sweating quite often leads to *sudamina*, and these, becoming inflamed, lead to *miliaria*. True *rheumatic erythematata* are much more common in the subacute cases than in the acute ones. *Purpuric* eruptions, again, are more often seen in aberrant types of the disease.

The only *pulmonary* complication of any consequence is pleurisy, and this

is by no means common if we preserve the usual strict criteria of physical signs for its recognition, and omit "pleurodynia," in which condition the pain is more often intercostal than pleural. Indeed it may be said that, in the absence of pericarditis and of severe endocarditis, rheumatic pleurisy is rare. Pneumonia also is unusual, but there is a condition of lung in severe rheumatic fever, again when complicated by grave endocardial, pericardial and pleural affections, which simulates it somewhat; the lung tissue is in a mixed state of congestion, collapse and cedema. A thin serous pleural exudate often accompanies this condition of the lung, and, no doubt, because of the associated pericarditis, it is more often found on the left than on the right side. Rheumatic *peritonitis* has been described in children.

Hyperpyrexia was formerly a much dreaded, and not very uncommon, complication. It is now quite rare. There is, indeed, by some modern observers, doubt thrown upon the rheumatic nature of the cases described under this term. May they, for example, have been fulminating cases of septicaemia or meningitis? It is clear that no case could nowadays be termed rheumatic hyperpyrexia unless lumbar puncture and blood culture findings were proved to be negative. But the strongest points in favour of regarding some, at least, of the cases as having been rheumatic, and not meningitic or septicæmic, are (1) the very high degree to which the temperature rose (107° to 110° F.); and (2) the fact that in some of the cases, at least, the clinical picture was definitely that of rheumatic fever before the event, and when recovery occurred as the result of prompt treatment it was similar afterwards. The condition arises suddenly in most cases, though in a few there is a suspicious prodromal amelioration in the pain, sweating and general discomfort. The temperature rises rapidly to 106° , and unless checked by cold applications it may quickly reach 109° or 110° F. Before this stage is reached the patient has become tremulous and excited, then delirious and then semi-comatose, with a dusky lividity of the face and a failing pulse. Most of such cases are fatal. If prompt treatment succeeds in lowering the pyrexia it may need to be resorted to again in a few minutes or hours, since recurrence of the condition is to be expected.

Course.—Before the introduction of salicylates the course of rheumatic fever was, in the words of Sir Thomas Watson, "six weeks." Nowadays it is much shorter; 10 days to 3 weeks, if we include the joint swellings, though the fever is generally over in a shorter period than this when the treatment is prompt and thorough. If residual joint inflammations prolong the course of the disease it is important to look for contributory causes, and especially for septic foci. Recrudescences are very common, especially if full treatment be relaxed too early. Complications necessarily prolong the course of the disease.

Convalescence is often tedious, and the resultant anæmia and heart weakness warn the careful practitioner not to attempt to hurry it. Rheumatic fever patients are as liable to *relapses* as they are to recrudescences, and it is no uncommon thing to see a patient slip again into almost as bad a state as he originally was, including, it may be, painful swelling of the very same joints as were first affected. The great danger of these relapses lies in the risk of heart inflammations arising during the subsequent attacks, when perchance the patient escaped them at the first.

Prognosis.—Recovery is the rule in this disease; *death during a first*

attack is very uncommon. When death occurs there is invariably serious carditis, especially myocarditis, and acute pulmonary complications (pleurisy and "rheumatic pneumonia") are usually present also. In rare cases, death occurs in a state of hyperpyrexia. When the attack supervenes upon old rheumatic carditis, the prognosis is less good, heart failure being more easily induced. But in general it may be said that rheumatic fever is serious, not from its case mortality, but from its crippling effect upon the heart. *Residual conditions* are almost entirely cardiac injuries and chiefly scarred valves and auricular fibrillation; rarely some degree of limitation of movement in joints.

RHEUMATIC FEVER IN CHILDREN.—The disease is very common in children, in whom, however, the clinical picture as above described is apt to be departed from in several respects. (1) The arthritis is a less marked feature; it may be absent altogether, and even when it is a troublesome element in the case, the degree of pain is prone to be disproportionate to the amount of redness and swelling of the joints, and may be muscular rather than articular. (2) Skin eruptions are relatively more common—various erythemata especially, but also purpura. (3) *Rheumatic "nodules"* are almost confined to children, having the same age-incidence as *chorea* (see p. 1724). These are discrete lumps, varying in size from small peas to horse-beans; symmetrical in distribution, they are found in the scalp, along the margins of the scapulæ and bones of the forearm, about the knuckles and elbows, and, less often, in other situations. They are sometimes tender and painful. They come and go. Occasionally they are present in large numbers; the case is then most likely to be subacute in type and very tedious in its course: they are, therefore, of grave prognostic import as to the ultimate state of the heart, being indicative of a "smouldering" endocarditis. They consist of elements approximating to the "essential" lesion of the disease to which reference has been already made. (4) But the most important difference observable between the disease in children and in adults is the fact that in the former the process is not seldom subacute in its onset and course, and for this reason frequently overlooked for a time. Add to this fact that the tendency to heart involvement in these subacute attacks is no less than in the more acute and more highly febrile bouts, and it is obvious that the recognition of this state of things is of the utmost importance. Unfortunately a large number of cases of subacute rheumatic endocarditis must needs arise without the possibility of prevention, but it is probable that a large number might also be prevented, or considerably modified, by prompt treatment of the subacute rheumatism in childhood which causes the injury. These attacks of subacute rheumatism are sometimes characterised by intercostal pain, sometimes by abdominal pain, sometimes by pain in the legs without special reference to the joints. There seems no doubt that so-called "growing pains" are often rheumatic in nature. In any child so affected the heart should be examined critically, and from time to time. The presence of sore throat, of acid sweats, of one of the erythemata, in conjunction with the above-named pains, should determine a decision to treat the child as suffering from the rheumatic process. The presence of nodules is decisive in a doubtful case.

Diagnosis.—Cases of the fully developed disease do not often lead to difficulty in diagnosis, given ordinary care on the part of the practitioner. A few diseases, however, require mention. (1) *Pyæmia* due to coccal infec-

tion may lead to some confusion, and the following differential points are worthy of notice. In septicæmia, when there is arthritis, the latter is usually constant in one or two joints, not fugitive and involving many as in rheumatic fever. Moreover, the joint changes tend to suppuration and permanent destruction of the joint structures. Blood cultures and joint-puncture fluids are not infrequently positive in pyæmia, whereas they are constantly negative in acute rheumatism. Rigors are common in pyæmia; in rheumatic fever they do not occur. If endocarditis complicates pyæmia, the heart infection is likely to lead to embolism, a condition not found in rheumatic fever. But between this type of streptococcal septicæmia and rheumatic fever all grades of cases are seen.

(2) In children *acute osteomyelitis* may be mistaken for rheumatism; rarely does the converse error arise. But the disease-process is nearly always much more severe, the temperature being much higher and showing greater oscillations. The painful part is generally the lower end of the femur or tibia, and careful examination reveals it to be epiphysal rather than arthritic. As in pyæmia, to which type of infection the disease really belongs, blood cultures are usually positive (*Staphylococcus aureus*).

(3) *Gonorrhœal arthritis* is not usually so acute a disease, nor is the patient often so ill as in rheumatic fever. The joints are fewer in number, and, as in pyæmia, the course of the individual involvement is much longer. The inflammation, too, affects peri-articular as well as articular structures; not seldom it involves adjacent tendon sheaths also. Gonococci may be isolated from the joint effusions. Although the presence of a urethral or vaginal discharge makes a diagnosis of gonorrhœal arthritis likely it does not prove it; and it must be remembered that the discharge not infrequently ceases temporarily with the onset of the arthritis.

(4) *Acute osteo-arthritis* is a rare disease, but when it occurs it produces a clinical picture that is probably closer to rheumatic fever than does any other disease-process. The patient is more often a woman than a man, and is generally older (30 to 60) than is the average case of rheumatic fever. The failure of salicylates in full doses to reduce the temperature, and to affect beneficially the course of the joint condition, should always raise doubts as to the nature of a supposed case of rheumatic fever. This differential point applies equally to diseases 1 to 3.

(5) *Gout*, when present in the acute arthritic form, may be mistaken for rheumatic fever; rarely does the converse happen. The patient is generally a man over 40 years of age; the number of joints involved is rarely more than two; the skin over these is generally dusky red in hue, and shining; there is often definite soft œdema. *The presence of severe pain when the affected joints are at rest is much in favour of gout.* The degree of fever is usually much less in proportion to the degree of joint inflammation than is the case in rheumatic fever. The presence of tophi may be taken as confirmatory of gout in a doubtful case.

(6) *Meningococcal meningitis with arthritis* rarely simulates rheumatic fever, but one of the writers (H.) has seen such a case, in which there were pungent acid sweats and purpura, and the resemblance to a case of severe rheumatic fever was for a time very close indeed.

Treatment.—(1) *General.*—With as much promptness as possible, the patient is put to bed, and is kept there until it is certain that the heart is un-

affected, or, if affected until it is certain that the inflammatory process has ceased to be active (see p. 948). The bed should be chosen carefully ; narrow enough to admit of easy nursing, and having a soft but firm mattress. The patient lies in blankets with a long flannel garment opening down the front, and having sleeves to the wrists ; this garment is changed as frequently as need be, according to the degree of sweating. The position of the patient is one of recumbency, with the affected joints supported in a position of maximum comfort. Movements of the limbs are generally best carried out by the patient's own efforts, and in all except severe cases, and where the heart is affected, movements of the body as a whole may also well be left to the patient. The basis of the *dict* should be milk diluted with water or alkaline mineral waters, and so long as the fever remains a marked feature of the case nothing should be added to this unless it be whey, peptonised milk or barley water. Abundance of fluids should be allowed, for a great deal of fluid is lost to the body through the profuse sweats. Imperial drink is very useful. As the fever declines, there may be added to the milk, oatmeal, vegetable soups and chocolate. Meat should be reserved for convalescence, and even then should be given very sparingly. Tea and coffee are best omitted altogether. Fruit is disallowed. Aperients are given as necessary.

In the matter of *drugs* there is a consensus of opinion that salicylic preparations deserve the name of specific remedies. They control the arthritis, cause the fever to decline, and cut short the course of the disease-process. They also lessen the tendency to relapses, and often render these abortive when they threaten. It may be quite true that they do not prevent the occurrence of endocarditis, nor affect this inflammatory process beneficially when once established, but a remedy which cuts short the course of a disease must necessarily, in an indirect measure, act as a deterrent in respect of its complications. Thus, by prompt exhibition of salicylates an attack of rheumatic fever may be almost resolved by the eighth day, at about which period in the disease acute endocarditis is specially liable to develop. Certain it is that pericarditis, and in particular pericarditis with liquid effusion, is much less common nowadays than it was in the pre-salicylic days ; so also is hyperpyrexia ; and it is unlikely, in view of the more general features of rheumatic fever and its incidence, that the disease-process has itself undergone any change during the past 50 years which is likely to account for these facts. The preparation of the drug which has become most popular and deservedly so, is sodium salicylate. *It should be given in sufficient quantities, and the doses should be distributed as evenly throughout the 24 hours as is compatible with securing good sleep for the patient.* At the onset of treatment of an acute case in an adult, 20 grains should be given every 2 hours during the day, and every 4 hours during the night (200 grains in the 24 hours). Many authorities advise that twice these amounts of sodium bicarbonate be added to the salicylate to prevent acidosis ; in the writers' opinion half the quantity of bicarbonate, i.e. 100 grains in the 24 hours, is sufficient and less likely to induce vomiting. If a child vomits a dose of salicylate, another given immediately will probably be retained. As the fever and pain diminish, these quantities may be given somewhat less frequently, a note being kept on the temperature chart of the total amount given in the 24 hours. In a child of 12 years or so, half these quantities may be given. If no amelioration follows these doses in 48 hours they should be increased by 50 per cent. (150

grains in 24 hours). If an exacerbation occurs, or a relapse threatens, after the dosage has been reduced, it should be at once adjusted to its original level. The drug is not unpleasant to take, and its taste is easily masked by liquorice water as a vehicle. Quite apart from the inestimable value of giving adequate doses so as to gain time, there is an additional value in this procedure from the point of view of diagnosis, for a *patient suffering from acute arthritis with fever, who is not considerably better after 48 hours' treatment by full doses of salicylates almost certainly is not suffering from rheumatic fever*. The diagnosis in these circumstances should be at once revised. It will be found that the great majority of patients tolerate the above specified doses of salicylates without ill-effects. In the few instances in which it produces vomiting, or intense depression, or delirium, or coma, or hæmaturia—symptoms thought from time to time to be toxic effects of the drug—either aspirin or salicin may be substituted. But care must be taken in deciding that such symptoms are really due to the salicylate and are not manifestations of the rheumatic poison. Modern synthetic preparations of sodium salicylate are fairly free from the contaminations which were formerly rather common. In the early stage of the disease it may be necessary to adopt more rapid palliative measures for the *severe pain*, especially if this prevents sleep. Nothing is better than opium, either as pulv. ipecac. et opii, grs. 10, or pil. saponis co., grs. 5. It is better to avoid phenazone and phenacetin. The treatment of heart complications is discussed elsewhere (Sect. XIII.). Against the occurrence of these complications, apart from the value of early and liberal use of salicylates, we seem to be powerless. But some authors attach importance to small blisters applied to the præcordium early in the disease.

Hyperpyrexia is met by prompt application of the cold pack, with volatile stimulants; the pack may need frequent renewal, and in extreme cases the water used for it must be iced. The most constant vigilance is necessary in such cases, which, as already stated, are happily rare nowadays.

In the treatment of prolonged cases of the disease the writers believe iodine (preferably not in the form of the potassium salt) to be useful, and especially so in cases complicated by serous inflammations, whether cardiac or other. Such experimental treatment of these prolonged cases by sera and vaccines as the writers have observed has not led them to employ either in any routine fashion. "Channels of entry" should, in protracted cases, be adequately dealt with as in (4).

(2) *Local*.—The position of optimum comfort of the affected joints has been already referred to. The use of splints for fixing the joints often gives relief. In the milder cases it suffices to wrap the joints in cotton-wool and bandage them lightly. In the more severe cases a lotion of tinct. opii, 1 fl. oz.; glycerin, 2 fl. oz.; water, 12 fl. oz.; sod. carb. to saturation, used hot, gives as much relief as anything. An alternative is one of the preparations of methyl salicylate, used freely, but without rubbing. Aspiration of the effusion is scarcely ever needed; its indication, indeed, should raise doubts as to the diagnosis.

(3) *During convalescence*.—Convalescence is generally slow, and should not be hurried. If the heart has suffered by direct inflammation, the recumbent position must be prolonged until it is certain that quiescence is established in that respect; this usually means from 4 to 6 weeks after the subsidence of the fever. The disastrous effects of attempting to hasten

convalescence in such cases are to be seen amongst patients who have been treated in institutions which advertise a false efficiency by reporting a "shorter average stay in hospital" than is the case in sister institutions. The transition from strict recumbency to a sitting posture should occupy a whole week, by the gradual addition of pillows, and the further return to ordinary active life should be graduated with care.

Tonic preparations, such as quinine and hypophosphites, are useful, but the tradition that iron is not well tolerated until late in convalescence—though the state of anæmia seems to indicate it—is confirmed by experience. Diet during convalescence has already been referred to. Massage and passive movements of the affected joints may be begun so soon as the inflammation has completely subsided.

(4) *Preventive treatment*.—Failing exact knowledge of the essential causative agent in rheumatic fever, no effective mode of prevention can at present be devised. But if there be a doubtful "channel of entry" present in any case, this should be dealt with in some radical fashion, in any patient who has had an attack, or is a member of a susceptible family. "Septic" tonsils should be enucleated, and an appendix which has at any time shown signs of inflammation should be removed.

ERYTHEMA NODOSUM

Ætiology.—Although this disease is a definite and easily recognisable clinical entity, it is still uncertain where it should be placed, when considered in relation to nosology or to ætiology. Formerly the favoured view was that the disease is a manifestation of acute rheumatism. Since, however, it is less often than not associated with the more definite criteria of acute rheumatism (arthritis, endo- and pericarditis), since it rarely recurs in the same patient, and since treatment by salicylates in full doses does not cut short its course, it is very doubtful if it should be regarded as a true rheumatic affection. A more recent view is that the disease is intimately related to tubercle: the lesions being toxic rather than actual areas of infection: the isolation of tubercle bacilli from them, originally reported, has not been confirmed. Alternative views are not lacking. By some erythema nodosum is thought to be an acute specific disease due to an unknown virus. Collis suggests that it is a type of hyper-reactive tissue response to different bacterial allergens and that the allergens responsible for erythema nodosum in London are commonly tuberculin and the toxin of hæmolytic streptococci.

It occurs more often in females than in males (according to Mackenzie, in the proportion of five to one), and the majority of cases are found between the ages of 10 and 30 years. There is no seasonal incidence. In the experience of the writer it is much more common in hospital than in private practice; this and some other observations suggest that bad feeding or insanitary conditions may contribute to the incidence of the affection.

Pathology.—There has been demonstrated a widespread arteriolitis in the subcutaneous fat, resolving without suppuration or residual fibrosis.

Symptoms.—The symptoms consist of: (i) the local lesions, and (ii) certain constitutional changes.

(i) The local lesions are bilateral and occur chiefly upon the lower

limbs ; indeed, in the great majority of the cases they are confined to these. When they appear on the arms they are most often found only in this situation, the patient is more often than not an adult, and the general symptoms are less like rheumatic manifestations than is the case in the more common variety of the disease. The lesions are round or oval swellings, usually confined to the extensor aspect of the limbs, affecting the shin regions chiefly, and varying in size from a large pea to half an orange. There may be two or three only on each leg, or, in severe cases, the greater part of the extensor surface may be covered by them. They involve the subcutaneous tissue as well as the skin. They are very tender to touch. On their first appearance they are deep red in colour, later they become purple in hue, and still later they often show a definite ecchymotic appearance—giving rise to the name *dermatitis contusiformis*. In bad cases there is a good deal of associated oedema of the surrounding tissues.

(ii) The general symptoms include a mild grade of fever (not constantly present), joint pains, malaise and sore throat. But many cases occur in which the local skin condition, with pain and tenderness, covers the whole of the symptomatology. Constipation is common, and is sometimes severe : in a case of the writer's, in a young man, there had been no action of the bowels for 10 days, and the patient had suffered from constipation all his life.

The course of the disease is from 2 to 3 weeks, but some mild cases get well, if treated, within a week.

Diagnosis.—The diagnosis is not difficult. Radcliffe-Crocker says that the lesions may be mistaken for syphilitic nodes : the distinction is made by the presence of other signs of syphilis, by the fact that the pains in the latter disease precede the appearance of the node through the skin, and by the lack of response to treatment by iodide of potassium. The lesions of Bazin's disease, though they occur on the legs much more than on the arms (as in *erythema nodosum*), though the sex and age are the same and though the association with tuberculosis is definite, are chronic and relapsing in character, and ulceration usually occurs.

Treatment.—Rest in bed, with the legs elevated, and general hygienic conditions, suffice to bring about spontaneous recovery in all cases. No drug has credit for cutting short the course of the disease. Recovery has been found to be quite as rapid when the patient is treated by small doses of hydrarg. c. cretâ with saline aperients, as when she is given full doses of sodium salicylate. As a local application lead lotion is perhaps the most soothing.

EPIDEMIC MYALGIA

Synonyms.—Epidemic or Infectious Pleurodynia ; Bornholm disease ; Epidemic diaphragmatic spasm ; Devil's grip.

Definition.—An acute infectious epidemic disease of short duration characterised by sudden onset of pain in the upper abdomen and lower thorax, pyrexia, sweating, and a tendency to relapse.

Ætiology.—The disease occurs usually in the late summer and autumn ; it mainly affects children under 15 years of age. The exciting cause is unknown ; infection appears to be spread by direct contact only, the incubation period

being 2 to 5 days; the patient remains infective so long as the pain persists. One attack may not confer lasting immunity.

Pathology.—Nothing is known of the pathology. No abnormality has been detected in those cases in which an exploratory laparotomy has been performed owing to mistaken diagnosis.

Clinical Features.—The onset is sudden, with acute spasmodic pain in the region of the xiphisternum and the attachment of the diaphragm, perhaps more on one side than the other. The pain leads to shallow rapid respiration, and is intensified by deep breathing, by yawning, sneezing or cough; a spasm during a period of quiescence may be induced by laughing. In adults, pain may also be complained of in the neck and extremities, and there may be some frontal headache. The temperature rises rapidly, perhaps to 101° F., and subsides within 24 hours. There is a marked tendency to a return of pain and pyrexia during 3 or 4 days, and the second attack may be the more severe. Profuse sweats are common, anorexia the rule, while vomiting and diarrhoea are seldom met with.

There are no physical signs, other than in the character of the respiration, of involvement of the pleura, lung or peritoneum. There may be some cutaneous hyperæsthesia and tenderness on pressure in the painful area, especially in the epigastrium. In some cases a leucocytosis occurs, and eosinophilia has been reported during convalescence. No abnormality has been detected on X-ray examination.

Complications are infrequent. Conjunctivitis, catarrh of the upper respiratory tract or orchitis have been reported in certain epidemics. There are no sequelæ. Prognosis is good.

Treatment.—The patient should be isolated, and remain in bed until 48 hours after the pyrexia and pain have subsided. Ordinary methods for the relief of pain are indicated.

HORDER.

A. E. GOW.

PINK DISEASE

Synonyms.—Infantile Acrodynia; Erythœdema; Vegetative Neurosis.

History.—The disease was first accurately described by Swift (Australia) in 1914, but Selter (Germany) had reported similar cases in 1903, and Swift records that he certainly saw examples of the disease when he was a resident at the Hospital for Sick Children, Great Ormond Street, in 1885. Feer (Zurich) is generally accepted in Europe as having described cases about the same time as Swift.

Ætiology.—The clinical syndrome is generally ascribed to the effects of a widely diffused toxin which shows a predilection for the autonomic nervous system. It frequently follows an acute infection of the upper respiratory tract and less often gastro-enteritis, either affording a possible portal of entry of a virus. Although not obviously infectious from case to case, small epidemics in localised areas have occurred in various parts of the world. This and a tendency to a seasonal incidence in spring and autumn offer obvious analogies with acute anterior poliomyelitis; and Mayerhofer has

described cases following this disease. Another theory favours a vitamin or other deficiency, but usually affected children have been well fed. Hypersensitivity to sunlight has also been put forward, but claims to a cure by the exclusion of sunlight in England are balanced by equally well supported claims to great benefit by exposure to sunshine in Australia. The balance of present evidence favours a virus. The disease occurs more especially in the temperate zones, affects the sexes equally and is almost limited to the period covered by the time of the primary dentition.

Pathology.—Apart from various findings due to secondary infections, the specific morbid pathology of the disease is said to include minor microscopical changes in medulla, cord and peripheral nerves. These consist of round-celled infiltration, demyelination and cedema. Some authorities maintain that even these changes are due to a non-specific terminal infection, or to secondary nutritional depletion.

Symptoms.—After a vague febrile onset, as intimated above, the infant fails to recover its previous vigour, and remains essentially miserable, with insomnia, muscular hypotonia, increasing loss of appetite and usually loss of weight. After a week or so some degree of stomatitis is commonly found, the child dribbles a lot, and just when the whole picture has been confidently ascribed to the effects of dentition the characteristic rash makes its appearance. This consists of three main features: a sweat rash, which may be present all over the trunk and proximal portions of the limbs; a curious "raw beef," puffy, non-pitting cedema of the hands, feet and frequently of the nose; and eventually various degrees of furunculosis and pyoderma. The condition of the mouth deteriorates, teeth may be shed (and swallowed), photophobia is often marked, and the child "burrows" in misery in the bed-clothes, constantly scratching and rubbing the hands and feet together. In severe cases the fingers and toes may be seriously bitten and the hair plucked out. Perspiration of a cold, clammy type is present and produces a "mousy" odour. Wasting and hypotonia become extreme, the child makes no effort to stand or walk, and prolapse of the rectum may occur. Signs of affection of the nervous system are shown by a persistent tachycardia—which is constant and varies in degree according to the severity and state of the disease—the tendon reflexes are frequently diminished or lost, and it may be possible to demonstrate a diminished sensitivity to pin-prick. The disease is usually afebrile save for the effects of complications, the blood pressure is said to be raised, although the determination of this is a matter of some difficulty, and there is frequently a leucocytosis.

Complications.—The upper respiratory tract infection may spread to affect the ears and, more seriously, to produce broncho-pneumonia, which is always a menace because of the risk of aspiration with an infected mouth. Pyelitis is not uncommon. Various local infections of the skin are almost invariable in a case of ordinary severity. Sequelæ, however, are unknown and relapses seldom occur.

Diagnosis.—There is no mistaking the disease once it is fully developed, and it obviously should be suspected whenever a young child appears to be seriously miserable for weeks at a time. Cases have been described with most of the classical symptoms, but without the rash or other skin changes. Tachycardia occurs in all cases, and unless the pulse rate is 140 or more a diagnosis of pink disease should not be made with confidence.

Prognosis.—In the absence of serious complications this is invariably good, and one attack confers immunity. Death is usually the result of some serious complication but occasionally is sudden after a period of increasing rate and irregularity of the pulse. It is suggested that in such cases the end is due to ventricular fibrillation.

Course.—The whole clinical picture may be spread over three to nine months, with some variation in the severity of the symptoms.

Treatment.—Since the exact causation is unknown, preventive measures are impossible, and most of the treatment has perforce to be symptomatic. Good nursing is essential but hospitalisation is undesirable; a well-trained nurse in the home is indicated as the patient's mother is almost invariably worn out. If weather permits the child's cot should be in the open air as much as possible, day and night. Silk or cotton clothing, frequently changed, is best, the eyes should be protected from glare, and some restraint may be necessary to prevent quite serious self-infliction of damage to the skin. The diet should be adequate, well-balanced, mostly liquid and offered cold, frequently and in small quantities. The troublesome anorexia can only be dealt with by skilful nursing. Deference to the deficiency theory of origin would indicate the administration of vitamin concentrates A, B, C and D, raw liver, and some yeast preparation, such as yestamin. Good results have been claimed for the injection of vitamin B₁ in massive doses, such as 1000 international units once a week. This has the merit of being a convenient way of treating an out-patient at a hospital. Whole vitamin B complex has also been used as well as individual constituents of the vitamin B series. Bellergal (one to three tablets daily for several days) is believed to counteract the effects of the disease upon the autonomic nervous system. Some sedative is essential and a mixture of chloral and bromide, according to the age, is probably the most suitable and should be used freely. For the skin a tepid bath (to which disinfectant, such as liq. hydrarg. perchlor., may well be added) once or twice daily, followed by a methylated spirit rub and copious powdering with a fine and talc (not starch) powder, will help to promote comfort. The irritation may be slightly allayed by calamine lotion or the use of menthol in paraffin (1 per cent.) dabbed on at night. The mouth requires great care. Giving the child swabs soaked in hydrogen peroxide may be recommended, and actual inflammatory lesions should be dabbed with methyl violet solution (1 per cent. in water). During convalescence an iron tonic and a change to the seaside help to promote complete cure.

ALAN MONCRIEFF.

SECTION III

DISEASES DUE TO METAZOA

A. DISEASES DUE TO TREMATODES OR FLUKES (DISTOMIASIS)

PARAMPHISTOMIASIS

Definition.—An invasion of man with amphistome flukes of the family *Paramphistomidae*. Two of these parasites are known. *Watsonius watsoni* (*Cladorchis watsoni*).—L. 8 to 10 mm. \times 4 to 5 mm.; Ova, 120 to 130 \times 75 to 80 μ . The parasite has a reddish-yellow colour when fresh and inhabits the duodenum and upper part of the small intestine. *Gastrodiscus hominis*.—L. 5 to 8 mm. \times 3 to 4 mm.; Ova, 150 \times 72 μ . The parasite has a large posterior disc by which it attaches itself to the mucous membrane of the bowel; it occurs in the cæcum and colon.

Symptoms.—Diarrhœa, with loose bilious stools in the case of the former parasite, and intestinal disturbances with diarrhœa in the latter. The eggs of both parasites are found in the fæces.

Treatment.—Carbon tetrachloride (3 c.c.) is probably specific.

FASCIOLIASIS

Definition.—An invasion of man and other animals with flukes of the family *Fasciolidae*. Several of these are known.

(1) *Fasciola hepatica* (*Distoma hepaticum*), the common liver fluke inhabiting the bile ducts of sheep and other mammals.—L. 20 to 30 mm. \times 8 to 13 mm. The ova are operculated and oval, measuring 130 to 145 \times 70 to 90 μ . From them miracidia emerge which develop into sporo-cysts, rediæ and cercariæ in snails of the species *Limnæa truncatula*; later the cercariæ encyst on grass stems and are subsequently eaten.

Symptoms.—Man is occasionally infected; light infections may be discovered accidentally during stool examinations, while severe cases may succumb to secondary cholangitis and liver abscess. In sheep the disease produces liver rot, which may be fatal.

Treatment.—Filix-mas administered in milk or capsules in a dose of 0.1 c.c. per kilo. and repeated in 24 hours will destroy adult, but not young, flukes. Good results are reported following a course of emetine injections. Carbon tetrachloride is effective in sheep and has been favourably reported on in human cases; it is, however, a dangerous drug where there is calcium deficiency. Success has followed the oral administration of large doses of magnesium sulphate combined with intravenous injections of stibosan.

(2) *Fasciolopsis buski* (*Distoma crassum*)—L. 30 to 70 mm. \times 12 to 14 mm; Ova, 120 to 130 \times 77 to 80 μ .—This giant fluke is found in China, Borneo, Malaya, Assam, Bengal and other regions in the East: it inhabits the small intestine, particularly the duodenum, producing focal lesions. The immature eggs are voided in the faeces, the miracidium matures in three to seven weeks and escapes through the operculum. It enters certain snails (*Planorbis carnosus*, *Segmentina nitidella*, etc.) and develops into sporocysts and rediae which generate cercariae; the latter encyst on water plants—water caltrop and water chestnut—man becoming infected by eating the corms. The cercariae encyst in the duodenum and mature.

Synonym.—The incubation period is three months. Initial symptoms include hypogastric pain, acid dyspepsia relieved by food, and diarrhoea. Later, asthenia, œdema of the face and extremities, ascites and dry, harsh skin develop.

Diagnosis.—The condition may simulate gastric ulcer or typhoid, and is diagnosed by finding the ova in the stools.

Treatment.—**PROPHYLACTIC.**—Consists of cooking water caltrops and water chestnuts and sterilisation of night soil.

CURATIVE.—Carbon tetrachloride (3 c.c.), hexyl-resorcinol (1 g.) and beta-naphthol (5–10 grains) are specifics.

PARAGONIMIASIS

Paragonimus westermani (*Distoma westermani*; *D. ringeri*)

Definition.—An invasion of the pulmonary tissues by the lung fluke, a member of the family *Troglorematidae*.

Ætiology.—Paragonimiasis occurs endemically in the Far East, especially Formosa, Japan, Korea and China. The adult flukes (7.5 to 12 mm. \times 4 to 6 mm.) form cysts in the lung, where the broad, oval, immature, operculated ova (80 to 118 \times 50 to 70 μ) escape via the bronchi and appear in the rusty brown sputum: they are also found in the faeces (40 per cent.). After attaining maturity the miracidium emerges, and invades a melaniid snail, especially *Melania libertina*, where it forms sporocysts, rediae and, later cercariae which encyst in the gills, liver and muscles of certain fresh-water crabs or cray fish—*Potamon obtusipes*, etc. If eaten by man the adolescaria emerges in the duodenum and migrates via the peritoneal cavity and diaphragm into the lung.

Pathology.—Host reaction results in cyst formation around the fluke, which generally communicates with adjacent bronchi, into which the eggs and anchovy-sauce cyst content are discharged. Pulmonary lesions consist of fibrosis, cystic dilatation of the bronchi, pseudo-pneumonia and tubercle-like abscesses. Similar cysts may involve the intestinal mucosa, bile ducts, peritoneum, pleura, brain, spleen and liver.

Symptoms.—These are divided as follows: (1) *General*, which include denitis and skin ulcerations; (2) *Thoracic*, characterised by cough and hæmoptysis with physical signs of broncho-pneumonia, pleural effusions or bronchiectasis; (3) *Abdominal*, with involvement of the liver, spleen, pancreas or intestine: if the latter, there is diarrhoea with eggs in the faeces; (4)

Cerebral, with Jacksonian epilepsy, hemiplegia, monoplegia, aphasia and eye symptoms. Headaches, loss of memory and insomnia may be present.

Diagnosis.—This is made by finding ova in the sputum or faeces. The complement-fixation reaction may be of assistance: eosinophilia is also present.

Prognosis.—Brain cases are fatal, and the outlook is bad in all severe infections.

Treatment.—Abstinence from eating raw fresh-water crab or cray fish prevents the disease. Emetine and tartar emetic temporarily relieve pulmonary symptoms, but cures are doubtful (Faust).

CLONORCHIASIS

Definition.—An invasion of the bile ducts of man and other mammals with trematode parasites of the family *Opisthorchidae*, occurring in Japan, Korea, China, etc.

Ætiology.—*Clonorchis sinensis* (*Distoma sinense*; *Opisthorchis sinensis*, etc.) is a spatulate fluke, measuring 10 to 20 mm. \times 2 to 5 mm. Its yellowish-brown ova are oval, possess a well-marked operculum, and measure from 27.3 to 35.1 \times 11.7 to 19.5 μ . Viable eggs are ingested by certain bithyniid snails (*Parafossarulus striatulus*, *Bithynia fuchsiana*), and the miracidia, penetrating the soft parts, form sporocysts, rediae and finally cercariae, which escape, and encyst in the flesh of certain freshwater fish of the family *Percidae*, *Gobiidae* and *Anabantidae*. When the mammalian host eats infected fish the adolescaria escapes in the duodenum and directly invades the bile ducts, especially the left, owing to its straighter course.

Pathology.—Initially infection leads to primary proliferation of the biliary epithelium and thickening of the duct wall; later this becomes greatly thickened, and finally cirrhosis of the liver with destruction of the parenchyma results (Faust). The pancreatic duct is sometimes involved.

Symptoms.—Mild cases may be symptomless, but the heavier infections show anorexia, epigastric pain, hepatomegaly, diarrhoea, wasting, jaundice, oedema and ascites.

Diagnosis.—This is made by finding the eggs in the faeces.

Prognosis.—This is dependent on the intensity of the infection; heavily infected cases occasionally die, but mild and moderate ones invariably survive unless some intercurrent disease develops.

Treatment.—Prevention lies in the cooking of freshwater fish before consumption. Tartar emetic intravenously possibly reduces the number of worms, while gentian, crystal and methyl violet reduce the intensity of infection as measured by the egg-cell count. Gentian violet is given as a keratin-coated pill (2½ grains) thrice daily after meals for ten days; for intravenous use 40 c.c. of an 0.5 to 1.0 per cent. solution is injected every other day; not more than 6 g. is advised (Faust).

When the liver is enlarged and tender, bile drainage may be accelerated by concentrated magnesium sulphate fed through a duodenal tube left *in situ* for several days. It decreases intra-biliary pressure and absorption of toxic material, but does not cure.

HETEROPHYIDIASIS

Definition.—Infection with flukes of the family *Heterophyidae*. Three genera occur in man.

(1) *Heterophyes heterophyes* (*Distoma heterophyes*, etc.). A minute intestinal fluke infesting man, the dog, cat, etc., in Egypt, measuring 1.0 to 1.7×0.3 to 0.4 mm. The oval, light-brown, operculated ova measure 28 to 30×15 to 17 μ . Though the life cycle is not completely known, the cercaria encyst in mullet (*Mugil cephalus*), the ingestion of which causes infection.

(2) *Heterophyes katsuradai* differs morphologically in the great size of its acetabulum, etc.

(3) *Metagonimus yokagawai*.—This pear-shaped fluke measures 1 to 2.5×0.4 to 0.75 mm., while its eggs closely resemble *H. heterophyes*, measuring 26.5 to 28×15.5 to 17 μ . The life cycle passes through *Melania libertina* and allied molluscs, the cercaria encysting in the edible fish, *Plectoglossus altivelis*.

(4) A number of other heterophyid flukes, including *Monorchotrema taichi*, *M. taihokui*, *Diorchitrema pseudocirrata* and *Heterophyes brevicata*, have been recorded by Africa and Garcia from Manila.

Pathology.—The flukes become attached to the intestinal mucosa by their suckers, inducing mild inflammatory reactions and eosinophilia.

Symptoms.—Mild digestive disturbances and diarrhoea with blood in the stools may result in severe infections. Often the condition is symptomless, the diagnosis being made by finding ova in the faeces. In their cases in Manila, Africa and Garcia have described a condition of cardiac heterophyidiasis, resembling cardiac beriberi, associated with sclerosis of the mitral valves and fibrosis of the myocardium; heterophyid ova were demonstrated in the local lesions.

Treatment.—Carbon tetrachloride, betanaphthol, thymol, the oleoresin of aspidium, or eucalyptus, castor oil and chloroform mixture are efficacious in eradicating the infection. To find the parasites, the stools must be strained through muslin.

SCHISTOSOMIASIS (BILHARZIASIS)

Definition.—Invasion of man with blood flukes of the family *Schistosomidae*. Three species are well known—*Schistosoma haematobium*, *S. mansoni* and *S. japonicum*. More rarely man may be affected by *S. bovis* and *S. matthei*. **Life cycle.**—The parasites inhabit the portal veins and their tributaries, depositing ova in the hollow viscera, whence they escape via the urine or faeces; on contact with water miracidia emerge, invade the appropriate molluscan intermediary, in which sporocysts and cercariae develop (Miyairi and Leiper). The latter invade the skin and find their way to the portal system, where the schistosomulae mature. The tuberculated male, originally a flattish fluke, has become rounded by inrolling of its edges to form the gynæcophoric canal, in which the thread-like female lies. Both sexes have an anterior, prehensile sucker and a posterior, suctorial sucker by which the worm maintains its position against the portal blood stream.

S. hæmatobium (*Bilharzia hæmatobia*) occurs in Africa and parts of Western Asia, etc. (σ 10 to 15 mm. \times 0.8 to 1.0 mm.; ρ 20 mm. \times 0.25 mm.). The ova have a sharp terminal spine and measure 120 to 160 \times 40 to 60 μ . The intermediary hosts vary considerably, being *Bulinus contortus*, etc., in Egypt, *Physopsis africana* in Natal, and *Planorbis melidjensis* in Portugal. *S. mansoni* is found in Africa, South America, etc. (σ 10 to 12 mm. \times 1.0 to 1.2 mm., ρ 12 to 16 \times 0.16 mm.). The ova have a lateral spine and measure 140 to 165 \times 60 to 70 μ . The intermediary host is *Planorbis boissyi* in Egypt, and *Physopsis africana* in Natal, etc. *S. japonicum* is confined to the Far East—Japan, China, Formosa and the Philippines (σ 12 to 20 mm. \times 0.5 to 0.55 mm. σ 15 to 26 mm. \times 0.3 mm.). The ova possess a lateral knob and measure 100 to 110 \times 55 to 65 μ . The intermediate hosts are *Katayama nosophora*, *K. formosana* and *Oncomelania hupensis*.

Pathology.—In *S. japonicum* and *S. mansoni* the worms are found in the portal system, especially its mesenteric branches, ova being deposited in large numbers in the colon and liver, and to a lesser degree in the small intestine, mesenteric glands, stomach, pancreas and rarely the spleen. In *S. hæmatobium* they wander still farther afield via the inferior hæmorrhoidal plexus into the pelvic plexuses of veins, especially the vesical, prostatic and uterine; eggs are deposited in the bladder, prostate, seminal vesicles, urethra, the lower third of the ureter, cervix and vagina. These plexuses communicate with the inferior vena cava; in consequence stray ova filter out into the lungs rather than the liver. Apart from toxic effects and suctional trauma produced by the schistosomes themselves, the egg deposits cause considerable local inflammatory reaction, at first giving rise to small pseudo-tubercles initially composed of giant cells, eosinophiles and round cells; later these disappear or are replaced by whorls of fibrous tissue in which degenerated and calcified eggs are found. The characteristic papillomata form as a combined result of irritative downgrowth of epithelium produced by toxic substances liberated from worms and ova, and submucous cellular accumulations pressing the mucosa upwards from below.

Special pathology.—*S. japonicum* and *S. mansoni* produce various colonic lesions, including round, whitish, submucous pseudo-tubercles, bilharzial colitis, and papillomata, which may slough off, leaving round ulcers. All these lesions may be visible with the sigmoidoscope. In addition, marked fibroid thickening and contractures of the bowel wall, mesentery and omentum sometimes occur. Periportal cirrhosis of the liver, which may or may not be associated with bilharzial splenomegaly, is met with. Other lesions include rectal papillomata, prolapse of the rectum, perineal granulomata and ischio-rectal fistulæ. In *S. mansoni* egg deposits in the spinal cord may produce myelitis, and granuloma of the brain simulating cerebral tumour is recorded in *S. japonicum*. In *S. hæmatobium* vesical lesions are dominant, but in addition there may be involvement of the ureters (lower third), chronic fibrosis of the prostate and seminal vesicles, bilharzial infiltration of the cervix, vagina and periurethral tissues with sinus formation, and granulomata of the penis and vulva. In the bladder the earliest lesions are minute petechiæ and round, yellowish, pseudo-tubercles studding its surface; later, papillomata and ulcers may develop, while chronic fibroid thickening and the so-called "sandy patches" are very characteristic of the chronic stages with calcified eggs. These lesions are demonstrable cystoscopically.

Pulmonary fibrosis associated with egg deposits is not uncommon, but involvement of the colon and liver is minimal.

Symptoms.—Three stages can be recognised: (1) invasive; (2) toxic or anaphylactoid; (3) localised disease (a) early, (b) late.

(1) *Invasive*.—The entry of cercariæ may give rise to transient rash and local irritation lasting 24 to 48 hours (Kabure disease).

(2) *Toxic or anaphylactoid*.—Within 2 to 8 weeks a clinical syndrome may appear, characterised by urticaria and an intense eosinophile leucocytosis; in addition there may be rigors, abdominal pain, enlarged, tender liver and spleen, dyspnoea, bronchitis, anorexia, diarrhoea and fever, lasting a few days to several weeks; the severe cases often simulate typhoid. This stage is most marked in *S. japonicum* (Katayama disease), but it is also described by Lawson in *S. mansoni* and by Fairley in *S. hæmatobium*.

(3) *Localised disease*.—Local features dependent on egg deposition in the bladder or colon are not generally apparent for three to nine months after infection. In *S. hæmatobium* early symptoms include scalding or frequent micturition, penile, perineal, suprapubic or loin discomfort or pain, and terminal hæmaturia, the blood being bright red and increased by exercise. At this stage the prostate may be congested and tender, cystoscopic examination shows the characteristic yellow, round pseudo-tubercles, and the urine contains leucocytes, erythrocytes and terminal-spined ova which may also appear in the faeces (40 per cent.). For years intermittent hæmaturia may be the only clinical manifestation, the subsequent course depending on such complications as carcinoma, cystitis with an alkaline urine containing much mucus, and renal involvement. In *S. mansoni* localised features may be absent or a chronic bilharzial dysentery may develop, characterised by colicky abdominal pain, the passage of blood and mucus, and tenesmus. Between attacks there is rectal discomfort, but the stools are solid, and coated with mucus, which may contain the characteristic lateral-spined ova. Later periportal cirrhosis and splenomegaly with ascites, etc., may supervene. In *S. japonicum* similar dysenteric symptoms are present. The chronic stage with cirrhosis and splenomegaly is characterised by weakness, emaciation, pallor, secondary anaemia, dilatation of the abdominal veins, and finally ascites and liver insufficiency.

Complications.—In *S. hæmatobium* there may be chronic nephritis or hydronephrosis due to backward pressure, or septic cystitis with pyonephrosis or ascending pyelonephritis. Carcinoma of the bladder, penis or vulva may also ensue, while bilharzia papillomata and vesical calculi are not uncommon. In *S. japonicum* and *S. mansoni* hepatic cirrhosis, liver insufficiency or carcinoma of the liver may supervene.

Diagnosis.—In the early toxic or anaphylactoid stage the diagnosis may be suggested by the intense eosinophilia and confirmed by the cercarial complement-fixation reaction (Fairley). In the localised stage the diagnosis is generally made by finding ova in the excreta, but the complement-fixation reaction and the cystoscopic or sigmoidoscopic findings often prove of considerable value. In examining for *S. mansoni* or *S. japonicum*, the mucus covering of the stool should be selected, and in *S. hæmatobium* the last few cubic centimetres of urine passed; several examinations may be necessary and eggs may be found in scrapings from the bowel wall obtained with a blunt curette during sigmoidoscopy, when ordinary faecal examinations are negative.

Prognosis.—The prognosis is bad in patients continuously exposed to infection, or in late cases when hepatic or renal insufficiency, septic infection or carcinoma has supervened.

Treatment.—**PROPHYLACTIC.**—This consists in curing the disease in man, in preventing excretal contamination of water, in destruction of snail vectors and in avoiding contact with infected water.

CURATIVE.—Two trivalent antimony compounds, tartar emetic and stibophen (fouadin), as well as emetine hydrochloride, exert a specific lethal action on the adult schistosome. During treatment rest in bed is advisable, especially if complications exist, but in Egypt and elsewhere often ambulatory treatment is alone practicable.

(1) *Tartar emetic*, first successfully introduced by Christopherson, is given intravenously in 10 c.c. of saline every second day, commencing with $\frac{1}{2}$ grain doses and increasing by $\frac{1}{2}$ grain until a maximum of 2 grains is attained. The solution must be freshly sterilised, and the total course for the adult should equal 30 grains. The drug kills the schistosomes, and viable ova rapidly disappear from the excreta. Cough, vomiting and toxic muscular pains may follow its administration, but the drug is generally well tolerated except in cases complicated by hepatic cirrhosis, renal involvement, sepsis, etc. Great care must be taken not to inject the solution into the tissues, as severe inflammation and necrosis result.

(2) *Stibophen (fouadin)* (antimony-pyrocatechin-disulphonate of sodium) should be given in an all-glass syringe in 6·3 per cent. solution; the total course consists of 40 c.c. administered in nine intramuscular injections extending over a period of 15 days.

The usual medical and surgical measures should be employed for complications as they arise, and rectal and other polyps which do not resolve with specific therapy may need excision with the electric cautery.

N. HAMILTON FAIRLEY.

B. DISEASES DUE TO CESTODES

TÆNIASIS—TAPE-WORMS

Definition.—Tæniasis is produced by different forms of tape-worms occurring either as adults in the intestine (intestinal tæniasis), or as the developmental stage in the muscles and other host tissues (somatic tæniasis).

INTESTINAL TÆNIASIS

(1) *Tænia solium* (Linnæus, 1758).—The pork tape-worm measures 2 to 3 metres in length. The head is globular and possesses 4 suckers, a rostellum and a double row of hooks. The uterus never has more than 12 lateral processes (diagnostic). The ova are spherical, 31 to 40 μ in diameter, having a thick-walled shell and an oncosphere with 3 pairs of hooklets. The cysticercus stage is passed in the pig (*Cysticercus cellulosæ*), and man becomes

infected by eating undercooked "measly" pork. Pickling and smoking do not kill cysticerci.

(2) *Tania saginata* (Goeze, 1782).—The beef tape-worm measures 3 to 4 metres in length. Its head is cubical with four suckers, but no armature; the uterus contains 15 or more lateral processes, thus differentiating it from *T. solium*, though its oval eggs, measuring $33-40 \times 20-30 \mu$, may be indistinguishable. The cysticercus stage is found in the ox (*Cysticercus bovis*) and man becomes infected by eating undercooked beef.

(3) *Dipylidium caninum* (Linnaeus, 1758).—A common tape-worm of the dog is occasionally found in man. Human infestation with *Tania confusa*, *Tania africana* and *Bertiella satyri* has been described on two or three occasions.

(4) *Hymenolepis nana*.—This dwarf tape-worm, which is common in Southern Europe, the Southern United States and India, inhabits the small intestine of man. It measures 2.5 to 4.0 cm. in length, has four hemispherical suckers and a short rostellum with a single row of hooks. The eggs measure 30 to 40 microns in diameter and contain an onchosphere. No intermediary host is required, as the eggs hatch out in the intestine. After penetrating the mucosa the embryos develop into cercocysts, return into the lumen of the bowel, become attached by their heads to the villi and develop into mature worms.

(5) *Diphyllbothrium latum* (Linnaeus, 1758) (*Tania lata*, etc.).—The broad, fish tape-worm, some 2 to 10 metres long, possesses an almond-shaped head, but no armature. The immature eggs are oval, operculated and measure $70 \times 45 \mu$. After three to five weeks' development in water the hexacanth embryo escapes and is ingested by some species of cyclops or allied crustacean in the body cavity of which it develops into a procercoid larva. Infected crustaceans must be swallowed by certain fish, i.e. before the plerocercoid larva develops. Man becomes infected by eating the undercooked, infected fish. Other species, such as *D. cordatum*, *D. parvum* and *D. houghtoni*, have been described on one or two occasions as has also *Diplogonoporus grandis* and *Braunia jassensis*.

Symptoms.—Symptoms may be absent, or gastro-intestinal disturbances, such as anorexia, voracious appetite, dyspepsia, abdominal pain, colic and diarrhoea may result. Neurasthenia in adults, and headache, convulsions and strabismus are described in children. Occasionally *D. latum* is associated with severe megalocytic anaemia.

Diagnosis.—The diagnosis is made by identifying the appropriate segments or ova in the excreta. Skin hypersensitiveness to tape-worm protein and eosinophilia may be present.

Treatment.—Filix mas and carbon tetrachloride are effective remedies for all the tape-worms, provided preliminary starvation and terminal purgation with salines be instituted. After a liquid diet, consisting of broths, orange juice, dextrose, etc., for two days, during which time the bowels are well opened, extractum filicis liquidum in 30 minim doses is given in gelatine capsules or emulsion at 8.0, 8.20 and 8.40 a.m. In obstinate cases an extra 30 minims may be given at 9 a.m. and 30 minims of oil of turpentine as well. Sodium or magnesium sulphate (gr. 240) is administered at 10 a.m., and all the motions subsequently passed must be carefully sieved and examined against a black background to identify the head; castor-oil must never be used as it dissolves out silicic acid and leads to poisoning. If the head is not recovered,

treatment may be repeated in ten days' time, or three months' interval may be allowed, by which time segments will have generally reappeared if the worm has survived. Carbon tetrachloride is given in capsules, the maximum adult dose being 3 c.c.; this is followed by a saline purge three hours later. Some report that it is advantageous to combine oil of chenopodium (1 c.c.) with carbon tetrachloride therapy, as in the treatment of ancylostomiasis.

The megalocytic anæmia associated with *D. latum* infestation responds satisfactorily to oral liver extract therapy, but recurs unless the worms be eradicated by specific drug treatment.

SOMATIC TÆNIASIS

(1) *Sparganum mansoni*.—This is the plerocercoid stage of *Diphyllbothrium mansoni* (Cobbold, 1882) which has a somewhat similar life-history to *D. latum*. The adult worm infests the intestine of the dog and cat, the ciliated embryo is ingested by *Cyclops leuckarti* where it develops into a procercoid larva. When swallowed by the second intermediate host, which may be a snake, bird or mammal, including man, the cyclops is digested, the liberated larva penetrates the stomach and, travelling under the peritoneum, reaches the deep somatic muscles, also the iliac fossa, lumbar region, pleura, urethra and eye where it multiplies asexually by transverse fission, many spargana resulting from a single plerocercoid (Faust). Ingestion of spargana-infested tissues by the dog and cat results in intestinal tæniasis, but the adult stage does not develop in man.

Symptoms.—Pain, swelling and oedema of the subcutaneous tissues and muscles sometimes occur, and in ocular sparganosis, which is common in the Tonkin delta, inflammation with pain, redness, oedema, lachrymation and ptosis may result. Human infection in China often follows the direct transference of spargana from infected frogs which are applied locally in the treatment of ulcers, etc. (Joyeux and Houdemer).

Diagnosis.—This is made by finding the unbranched sparganum larvæ embedded by their scolices in a slimy matrix in the tissues.

Treatment.—Where possible the parasite is removed surgically.

(2) *Sparganum proliferum* (Ijuma, 1905).—This species affects man in Japan, innumerable spargana producing nodules and honeycombing of the tissues, and elephantiasis if the lymph channels be involved. The adult stage and life cycle are unknown.

(3) *Tænia solium*.—The cysticercus stage of *T. solium*, i.e. cysticercosis, is occasionally found in man who may or may not have harboured the adult parasite. The cyst, which is generally surrounded by a fibrous-tissue capsule, consists of an opalescent bladder containing a single evaginated head with hooklets. Various tissues, including the brain and its ventricles, the liver, lungs, orbit and the somatic muscles and heart, may be involved. It occurs in Europe, Africa and Madagascar, and in soldiers returning from India and Egypt. Macarthur has found it to be a common source of epilepsy. Man probably acquires the disease by auto-infection, or eating uncooked food, such as lettuce, to which dried segments of *T. solium* are adherent.

Symptoms.—Subcutaneous nodules ($\frac{1}{2} \times 2$ cm.), muscular weakness, cramp and pains may be encountered, also Jacksonian epilepsy, petit mal, various psychoses and occasionally focal lesions of different types, if the brain

be involved (*Cysticercus cellulosæ*). The diagnosis is established by biopsy of a subcutaneous cyst, or X-ray examination revealing calcified nodules in the muscles. Ophthalmoscopic examination may show retinal lesions, while eosinophilia and skin hypersensitiveness and positive complement-fixation reactions with tænia antigens may be found. Accessible cysts can be excised, but the prognosis is bad if the brain be involved. The most dangerous period is the sixth to the eighth year, when cerebral disturbances most frequently occur. Mental deterioration and death frequently result, but even those developing cerebral cysts may recover. Fits should be controlled by luminal and bromide.

(4) *Tænia multiceps* (Lescq, 1780).—*Cænurus cerebralis*, the cystic stage of the canine tape-worm, *T. multiceps*, commonly affects the brain of goats and sheep; it has been recorded in man, producing epilepsy and aphasia.

(5) *Echinococcus granulosus* (Batch, 1786).—This small tape-worm (2.5 to 6 mm. in length) inhabits the intestines of dogs, jackals and wolves; it consists of a head with four suckers, a rostellum and hooklets and three or four segments, of which only the terminal one is gravid. In the intermediate hosts, which include sheep, cattle, pigs and man, hydatid disease is produced. Man becomes infested from swallowing water and uncooked vegetables, etc., contaminated with infected canine faeces, or by handling and fondling infected dogs. Hydatid disease is frequently contracted in childhood and is most common in sheep-breeding countries like Australia, New Zealand, the Argentine and South Africa; it also occurs in Iceland but is less frequently encountered in Europe.

After the egg is swallowed, the six-hooked embryo escapes from its shell, traverses the intestinal wall, invades the blood vessels, and metastasises generally in the liver, but less frequently in the lungs, brain, bones, and muscles, etc., where it loses its hooks and forms a cyst, the wall of which consists of two layers, a laminated outer layer, the ectocyst, and a granular inner layer, the endocyst. As the cyst grows, it exerts mechanical pressure and toxic effects on adjacent host tissue, resulting in inflammatory reaction and the formation of a fibrous tissue capsule known as the adventitia. Endogenous budding from the granular layer of the cyst results in the formation of brood capsules, scolices, and daughter and granddaughter cysts. Exogenous budding sometimes occurs, especially in bone, while atypical development in viscera like the liver may result in alveolar or multilocular types of hydatid. It is improbable that a second parasite, *E. multilocularis*, exists.

Symptoms.—The clinical picture is very varied. Cysts may be symptomless for many years until pressure effects are produced, or they may rupture or suppurate with the production of acute illness. Rupture into a vein may lead to sudden death from an embolus of daughter cysts, or to an anaphylactic syndrome characterised by injected conjunctivæ, lachrymation, vasomotor collapse, urticaria, œdema, respiratory distress and eosinophilia. Rupture into the peritoneal cavity may produce an acute abdominal crisis followed by peritoneal echinococcosis, secondary cysts developing from scattered scolices, or if the cyst rupture into a bronchus natural cure may ensue. Suppuration, especially of liver cysts, is not uncommon, while in some 30 per cent. of cases their degeneration and death with subsequent calcification lead to natural cure. The inferior aspect of the right half of the liver is the commonest site affected, while the right lung is three times as often involved as the left.

Brain cysts closely simulate cerebral tumour, while echinococcosis of bone, owing to its rapid exogenous growth, often leads to a fatal issue, especially when the pelvis and vertebral column are involved ; a pressure myelitis may result.

Diagnosis.—A history of contact with dogs in childhood is important ; hydatid thrill, if present, is pathognomonic. Collapsed cysts, membrane, scolices and hooklets may be coughed up or passed per rectum, while the aspiration of a clear watery fluid containing considerable amounts of sodium chloride and hydatid elements clinches the diagnosis. Aspiration, however, should never be carried out in lung cysts except on the operating-table owing to the danger of drowning from rupture into the bronchial tract. X-ray examination is of considerable importance in localising liver and lung cysts, while the complement-fixation and precipitin reactions and the intradermal test have greatly increased the percentage of cases correctly diagnosed before operation. Eosinophilia may occur, especially if a cyst has recently ruptured.

Treatment.—No medical treatment is available except for the anaphylactic syndrome, when adrenaline (10 min. of 1 in 1000 solution) should be administered. As a rule, calcified cysts should not be operated on. After the injection of formalin to kill scolices in hepatic cysts the contents should be evacuated and the adventitia sewn up in smaller sized cysts ; suppurating and large cysts must be drained. Special care must be taken to prevent soiling of the peritoneum with the cyst contents in hepatic hydatid, as secondary peritoneal echinococcosis is liable to develop.

N. HAMILTON FAIRLEY.

C. DISEASES DUE TO NEMATODES (ROUND-WORMS)

STRONGYLOIDIASIS

Strongyloides stercoralis (Bavay, 1876).—A common tropical parasite of man, the female worms living in the jejunum and duodenum, and in massive infections invading the bile and pancreatic ducts, the stomach and colon.

Ætiology.—The eggs hatch out rhabditiform larvæ which appear in the faeces : rarely, where intense diarrhoea is present, the eggs ($50-80 \times 30-34 \mu$), which resemble ancylostome ova, may be found. The rhabditiform larvæ give rise either directly, or indirectly through a sexual circle, to filariform larvæ which invade the skin or mucosa and follow a similar route to ancylostomes proceeding via the lung to the intestine.

Pathology.—Intestinal catarrh or an enteritis, with extensive erosions of the mucosa, giving rise to a "beefsteak" appearance, may occur in heavy infections.

Symptoms.—Initial dermatitis and lung symptoms may be seen during the first few days. Mild infections show no symptoms ; severer infections may present epigastric discomfort after meals, flatulence and diarrhoea which occasionally is very intractable. Occult blood may occur, urticaria and oedema sometimes develop at the site of entry of infective larvæ, and dermal sensitivity can be demonstrated to strongyloid extracts (Fülleborn).

Diagnosis.—This is made by finding the rhabditiform larvæ in the stools, which should be mixed with water and strained through muslin. Hook-worm embryos have a longer pre-œsophageal mouth cavity and occur within the egg.

Treatment.—Gentian violet, introduced as a specific by De Langar, is given as a keratin-coated pill (1 grain) thrice daily before food until a course of 50 grains has been taken. In intractable cases, 25 c.c. of a 1 per cent. aqueous solution can be administered through a duodenal tube. For the intravenous route 25 c.c. of an 0.5 per cent. solution is recommended on alternate days for ten days. Though favourably reported on, gentian violet treatment by no means always cures.

Allied helminths, including *Rhabditis pellio* (Schneider, 1886) and *Turbatrix aceti* (Müller, 1783), the common vinegar worm, have been reported in the vaginal exudate and urine of women.

FILARIASIS

An invasion of man by members of the family *Filariidæ*. Several species are known to infest man, *Filaria bancrofti* or *Wuchereria bancrofti*, *Filaria loa* or *Loa loa*, *Filaria perstans* or *Acanthocheilimonema perstans* transmitted by *Culicoides austeni*, and *Filaria ozzardi* or *Mansonella ozzardi*, the insect vector being *Culicoides furens*. Only the first two are of clinical importance. Two larval *Filariidæ* are known in which the adults have not been found—*Microfilaria malaya* (Brug, 1927) occurring in the peripheral blood at night, and *Agamofilaria streptocerca* (Macfie and Corson, 1922) found commonly in the skin of natives on the Gold Coast.

(1) *Filaria bancrofti* (Cobbold, 1877).—This parasite has a widespread tropical distribution, being especially common in India, the West Indies, Porto Rico, Southern China and the Pacific Islands. The adults are like fine catgut (σ 30–40 mm. long; \varnothing 76–100 mm. \times 0.2 mm.); they inhabit the lymphatics and periglandular lymphatic tissue, and produce embryos which subsequently invade the blood stream, living in the lungs and thoracic blood vessels by day and appearing in the peripheral blood only at night—nocturnal periodicity. The embryos are enclosed in a loose sheath and measure $230\text{--}320 \times 7.5\text{--}10 \mu$. As Manson first showed, the intermediate host is a mosquito (chiefly *Culex fatigans*), which sucks the embryos out of the blood at night; metamorphosis subsequently takes place in the thoracic muscles. The mature embryos are inoculated into man via the proboscis (Low). Development in the insect vector takes from 10 to 40 days, depending on the temperature, etc. In the Pacific two filaria zones are encountered. Filariasis in New Guinea and New Britain is of the usual nocturnal type and transmission is chiefly by *Culex fatigans*. In islands east of 170° east longitude filaria is transmitted mainly by the day-biting mosquito, *Aedes scutellaris pseudoscutellaris*, and is non-periodic in type. This holds in the Samoan, Wallis, Friendly, Fijian, Ellice, Gilbert and Society island groups. Though there are no morphological differences between the adults and microfilariae of the nocturnal and non-periodic types of *Filaria bancrofti*, it is still possible they may represent different strains or subspecies.

Pathology.—The parent worms often produce little obvious damage

the infection then being recognised only by the presence of microfilariae in the blood. Pathological changes, associated with the presence of filaria worms, however, may be found in the tissues of such patients (O'Connor and Hulse), notwithstanding the absence of symptoms, while in others, especially when hyperinfection has extended over many years, the most gross and grotesque pathological manifestations may be found. The various changes in the lymphatics and lymph glands are partly of mechanical origin and partly attributable to the effects of helminthic toxins and secondary streptococcal invaders, which induce lymphangitis with resulting lymph stasis and lymph oedema. Lymph oedema and inflammatory tissue reaction ensure an increased protein content of the tissue fluids; this stimulates growth and results in hyperplasia of the skin and subcutaneous tissues, ultimately leading to elephantiasis. Recurring lymphangitis and blocking of the lymphatics may result in death of adult worms, but even if this does not happen, obstruction of the lumina of the lymphatics proximal to the worms will prevent the escape of microfilariae into the circulation. These are the probable reasons why microfilariae are no longer demonstrable in the blood of patients with elephantiasis.

Symptoms.—The incubation period is variable. Some six months to two years may elapse before early clinical features such as urticarial swellings, filarial nodules and thickened lymph cords, lymphangitis, adenitis, epididymo-orchitis, or lymph scrotum appear. Eosinophilia and skin hypersensitivity to *Dirofilaria immitis* antigen are generally present at this time, but no microfilariae are demonstrable in the blood. Excision of a nodule and subsequent microscopic examination may reveal adult worms. As in loa loa infestation, it may be some years before embryos are demonstrable, even when considerable quantities of blood are examined.

Lymphangitis is associated with rigors, high temperature, tender enlargement of the lymphatic glands, red lines in the course of the lymphatics, and inflammatory swelling of the affected tissues. The "elephantoid" fever usually lasts one to three days, but occasionally it may persist for several weeks. The filarial nodules described by O'Connor originate as a local tissue reaction around dead filarial worms located in the lymphatics; from here red lines caused by inflamed lymphatic vessels may radiate down the limb. The lymphangitis is well defined, being dull red, tense and oedematous.

Enlarged groin glands are common and if associated with a mass of varicose lymphatics (lymphatic varix) may be mistaken for a hernia. Microfilariae are often found in the aspirated lymph. If lymphangitis ensues there is much local inflammatory swelling, tenderness and pain. The axillary, epitrochlear and cervical glands occasionally become enlarged, especially in non-periodic filaria, while enlargement of the deep-seated glands—iliac, lumbar, mesenteric, retroperitoneal and thoracic—sometimes occurs. Living or calcified worms may be found in such glands, and secondary coccal infection may lead to fatal septicaemia. Involvement of the retroperitoneal lymphatics may cause abdominal pain, associated with tenderness and rigidity of the abdominal muscles, vomiting, hiccough and fever; death from streptococcal peritonitis may follow. Endemic funiculitis or lymphangitis of the spermatic cord is often associated with lymphantietasis, and is characterised by acute tenderness and local inflammation of the scrotum and cord. Filarial epididymo-orchitis is also not uncommon. It produces fever, shivering and pain in the

testicle, which rapidly enlarges and is associated with exudation of fluid into the tunica vaginalis. The swelling subsides in a few days, but permanent thickening and a filarial hydrocele or chylocele may result. Recurrences are common. Lymph scrotum is due to an inflammation of the scrotal lymphatics, which may become dilated and tortuous, and form small vesicles exuding lymph containing microfilariae. Recurrent attacks lead to elephantiasis. Chyluria results from obstruction and dilatation of the thoracic duct itself or of some of the chyle-carrying intestinal lymph vessels. Subsequent rupture of dilated lymphatics into the pelvis of the kidney, ureters or bladder leads to chyluria, or, if chyle escapes into the peritoneal cavity, to chylous ascites.

Elephantiasis results in people repeatedly exposed over long periods of time. The lower limbs are most frequently involved, next the scrotum, and next the arms. Elephantiasis of the mammae, vulva and penis are rare. The condition is generally preceded by recurrent attacks of lymphangitis with fever and secondary dermatitis and cellulitis. Occasionally such a history is lacking. Different clinical types are described varying from slight uniform enlargement of the limbs with perceptible thickening of the skin, to gross enlargement with characteristic elephantoid appearance and deformity. The skin becomes coarse and thickened; later, indolent ulceration or abscesses may form, or a coarse warty appearance develops (Elephantiasis verrucosa). Finally the skin becomes leathery in consistency and thrown into rugae, while the hypertrophy of the subcutaneous tissues become so great that the patient is practically immobilised by mere increase in the weight of the lower limbs or scrotum. Patients inflicted with this condition may live for many years, finally dying from intercurrent disease.

Diagnosis.—Prior to the appearance of embryos in the blood, eosinophilia associated with a positive intradermal skin test will suggest the diagnosis. If nodules are present, biopsy should be performed and examination made for the presence of adult filaria in tissue section. When searching for embryos, blood should be collected at the appropriate time (about 10 to 12 p.m. in the nocturnal type), and as much as 20 c.mm. of blood examined in thick films. The fact that the lymphangitis often originates in a nodule in the course of the lymphatic vessels and is of retrograde not the ordinary ascending type, should suggest a filarial origin.

Filarial elephantiasis should be distinguished from the familial type of elephantiasis known as Milroy's disease, and from elephantiasis secondary to recurrent streptococcal lymphangitis, or blockage associated with tuberculosis or carcinoma of the lymph glands or surgical excision.

Treatment.—Prophylaxis depends on mosquito destruction and the use of mosquito nets, etc. No specific drug treatment has yet been discovered for man, but certain trivalent and pentavalent organic antimony compounds have been favourably reported on in animal filariasis. Fouadin kills the microfilariae in dogs infected with *Dirofilaria immitis* but not the adult worms, and neostam (stibamine glucoside) has recently been reported as curing filariasis (*Litomosoides carini*) in the cotton rat by destroying the adult parasites. The application of an ethyl chloride spray to focal points has been advocated to abort lymphangitis. If secondary streptococcal infection has supervened, sulphonamide therapy is indicated. Surgical intervention may be necessary for septic complications, such as filaria abscess and various

elephantoid conditions. In elephantiasis of the legs elastic bandaging, massage and rest, with elevation of the limbs, are desirable. Elastic stockings should be washable, porous, and made to fit, extending from the dorsum of the foot to above the knee.

(2) *Loa loa* (Cobbold, 1864).—Human infestations with this parasite occur in West Africa. The adults inhabit the subcutaneous and retroperitoneal tissues, while the sheathed embryos have a diurnal periodicity (9 a.m. to 9 p.m.); several years may elapse before embryos appear in the peripheral blood. Transmission is by certain species of mango-fly (*Chrysops dimidiata* and *C. silacea*) which feed in the daytime. Clinically the worms give rise to urticarial eruptions and puffy, painless, white swellings the size of a hen's egg, lasting two to three days, known as Calabar swellings. These are due to an oedema of the subcutaneous tissue and probably represent an anaphylactoid reaction to helminthic products or toxins. Leucocytosis associated with a marked eosinophilia (20 to 60 per cent.) is characteristic, and dermal hypersensitiveness to diro-filarial extract is shown in almost every case. Positive complement-fixation reactions are also given with diro-filarial alcoholic extracts. Neuritic pains may also be complained of. Not infrequently the worms appear about the eye, and in their migration across the conjunctivæ give rise to transient conjunctivitis and lachrymation. Where visible, the worm should be surgically removed under local anæsthesia.

ONCHOCERCIASIS

Onchocerca volvulus (Leuckart, 1893).—This nematode, found on the west coast of Africa, inhabits the subcutaneous or connective tissues of man, often giving rise to nodular, subcutaneous, cystic tumours, 1 to 10 cm. in diameter, over which the skin is generally movable, and in which lie entangled masses of worms and embryos encased in dense fibrous tissue. The swellings are particularly common around the elbows, knees, ribs, iliac crests and great trochanter. Unsheathed microfilariae may occasionally be demonstrated in the skin, especially of the loin and thigh, as well as in the circulatory blood and subcutaneous lymph channels, even though no evidence of disease exists. Dermal lesions, including achromia, xeroderma and pseudo-ichthyosis, are attributed to embryos located in the skin (Laigret). Pruritus may be intense, especially at night. *Onchocerca* tumours of the head are not infrequently associated with ocular complications. Blindness may result from retinochoroiditis or punctate iritis when embryos are found in the anterior chamber. Blacklock has shown that transmission is by the buffalo gnat, *Simulium damnosum*. Localised tumours may be removed under local anæsthesia.

The parasite called *Onchocerca cæcutiens* (Brumpt, 1919) is found in Guatemala and Mexico. Its status as a distinct species has for some time been doubtful, and the recent work of Strong indicates it is the South American form of *O. volvulus*. It produces flat nodes (Guatemala nodules) up to 2 cm. in diameter, especially affecting the scalp and face, and an eruption known as "coastal erysipelas," associated with pain, tumefaction and fever may result from secondary streptococcal infection of the skin due to scratching, the irritability being caused by microfilariae in the corium. More important are the ocular lesions caused by microfilariae, piercing the capsule of the nodules

and invading the tissues of the eye, producing conjunctivitis, punctate-iritis, keratitis and choroiditis. Blindness commonly follows (Strong). An eosinophile leucocytosis is the rule. Diagnosis is made by demonstrating the microfilarie in the milky fluid aspirated from the nodules, or in adjacent pieces of skin shaved off and teased up in saline at 37° C. for microscopical examination. Transmission is by three different species of *Simulium*, the coffee flies living at a height of 2500-5000 feet. The nodules should be excised whenever possible, especially those in the vicinity of the eye. Some improvement in the ocular condition may follow this procedure.

DRACONTIASIS

Dracunculus medincensis (Linnaeus, 1758).—Guinea-worm disease is common in India, Persia and Africa. The adult female, measuring 40-120 cm. \times 0.5-1.7 mm., inhabits the subcutaneous and interstitial tissues, and takes some 12 months to reach the skin where it secretes some toxin producing a blister which later ulcerates, and permits, on contact with water, the reflex discharge of embryos from the prolapsed uterus which perforates the base of the ulcer. The worm itself is often surrounded by a fibrous-tissue canal. Fedtschenko, in 1879, produced evidence that a cyclops was the intermediate host. Man becomes infected by swallowing these crustaceans in drinking water.

Pathology.—Three factors are responsible for pathological lesions, namely, the worm, the embryos and secondary bacterial invaders. The toxic substance responsible for blister formation may, if absorbed, lead to anaphylactoid symptoms. Premature ejaculation of embryos may produce subacute sterile abscess. Bacterial invaders, especially *Staphylococcus aureus*, *Bacillus coli* and streptococci are responsible for acute abscess, cellulitis, bubo, synovitis, arthritis and septicæmia; these complications almost invariably result from the retraction into the tissues of a taut, elastic worm, broken during efforts to extract it.

Symptoms.—Prodromal symptoms consist of an itchy, urticarial eruption (40 per cent.) which may be associated with vasomotor collapse, vomiting, diarrhoea, dyspnoea and high eosinophilia, followed a few hours later by blister formation and ulceration (Fairley). The lower extremities are commonly involved (86.5 per cent.), and in decreasing frequency the arms, trunk, buttock and scrotum. Septic complications are frequent, and contracture of tendons and fibrous ankylosis of joints sometimes result. Neuritis and muscular rheumatism may be produced by calcified worms, which on X-ray examination show a pathognomonic, convoluted, moniliform shadow.

Treatment.—This depends on the stage at which the patient is seen. Anaphylactoid symptoms are best treated by injections of adrenaline (min. x. of a 1:1000 solution). A blister, if present, should be aspirated. Once an ulcer has formed it must be treated with antiseptic dressings and the worm subsequently extracted either by intermittent traction and massage, or by multiple incisions under local anaesthesia. The outline of the worm becomes more obvious if the tissues are sprayed with ethyl chloride. When the worm is closely convoluted the whole area may be excised *en masse*. The old method of gradual extraction by winding round a match and daily douching

with water until the uterus is emptied still has its advocates. Localised abscess must be treated by passing a probe through the sinus and slitting up the canal in which the worm lies. Other complications are treated along general surgical lines.

TRICHINIASIS

Definition.—A disease produced by the embryos of *Trichinella spiralis* (Owen, 1835) during their migration from the human intestine to the muscles.

Ætiology.—Infection is acquired by eating raw or underdone pork in which the larvæ have encysted. After the cyst walls have been dissolved by the gastric juice the embryos mature and breed in the small intestine. The gravid female bores into the mucosa, depositing hundreds of viviparous larvæ ($100 \times 6 \mu$) which reach the muscles from about the ninth to the fortieth day via the liver, lung and left heart. The adults are small (σ 1.4–1.6 mm. \times 0.04 mm.; ρ 3–4 mm. \times 0.6 mm.) and live only a few weeks, whereas encysted larvæ may survive for 25 years, though they often calcify within six months. Rats act as reservoir hosts.

Symptoms.—For the first week during the invasion period gastrointestinal symptoms develop with nausea, vomiting, colic and diarrhoea with perhaps blood and mucus; then when migration of larvæ commences myositis of the tongue, laryngeal and intercostal muscles and the diaphragm occurs, giving rise to difficulty of swallowing, speech and respiration. The muscles of the jaws, arms, legs and abdomen may also be involved with stiffness and pain; the affected areas are exquisitely tender and hard to the touch. Oedema, especially of the face, urticaria, leucocytosis with high eosinophilia, prolonged remittent fever (102° – 104° F.) and sweating are characteristic. Pulmonary features are common, and occasionally hæmoptysis occurs. Cachexia develops and, finally, during the period of larval encystment, the patient may succumb from toxæmia with respiratory disturbance and coma.

Diagnosis.—Early, the disease may be mistaken for ptomaine poisoning, enteritis or dysentery, and later for rheumatic fever or typhoid. The intense eosinophilia should arouse suspicion, while later biopsy of a piece of the affected muscle such as the deltoid at its tendinous insertion will often reveal precystic or encysted larvæ. Embryos may be found in the blood, especially from the twelfth to the twentieth day, by laking it with ten volumes of 3 per cent. acetic acid and centrifuging the deposit. Intradermal and precipitin tests are often positive to an antigen manufactured from the embryos (Bachman). At a late stage, calcified cysts may sometimes be visualised by X-ray.

Prognosis.—This largely depends on the intensity of the infection, the mortality rate varying in different outbreaks from 1 to 30 per cent. Convalescence is often slow and muscular atrophy may follow.

Treatment.—**PROPHYLACTIC.**—This depends on careful meat inspection, and adequate boiling of pork; curing by smoking and salting is ineffective. Special care should be taken at autopsy to prevent infection.

CURATIVE.—No specific treatment is known, but every effort should be made to expel the adult worms. Purgatives and glycerin, santonin, thymol and turpentine are employed for this purpose.

CEPHALOGASTOMIASIS

(1) *Cephalogastomum apiosomum* (Willach, 1891).—This nematode frequently affects certain anthropoid apes and monkeys in West Africa, and not uncommonly man in Northern Nigeria. The rhabditiform larvæ exsheathe in the cæcum, invade the bowel wall and give rise to inflammatory nodules in which they develop; later they erupt into the intestine and mature. Dysentery-like symptoms, with hæmorrhage and occasionally peritonitis and septicæmia, may result. The ova are indistinguishable from ancylostome eggs, but fortunately thymol, oil of chenopodium and carbon tetrachloride are specific for the adults (Faust).

(2) *Cephalogastomum stephanostomum* (Raillet and Henry, 1909).—The adult worms present minor differences, and in the only human case recorded, by Thomas in Manaos, Brazil, nodules were found in the ileum as well as in the colon.

ANCYLOSTOMIASIS

Synonyms.—Uncinariasis; Hookworm Disease.

Definition.—Ancylostomiasis is caused by members of the family *Ancylostomidæ*. Five species may affect man—*Ancylostoma duodenale* (Dubini, 1843), *Necator americanus* (Stiles, 1902), *Ancylostoma malayanum* (Alessandrini, 1905), *Ancylostoma braziliense* (Gomez de Faria, 1910), and the *Ancylostoma caninum* (Ercolani, 1859). The first two species commonly affect man, the third and fourth rarely, while the larvæ of the fifth may cause creeping eruption.

Ætiology.—*A. duodenale*.—Adults ♂ 8–10 mm.×0.4–0.5 mm.; ♀ 12–18 mm.×1 mm. Ova are elliptical, thin-shelled containing vitellus, segmented into 2 to 8 spherules, and measure 55–65×32–45 μ . *N. americanus*.—Adults ♂ 7–9 mm.×0.3 mm.; ♀ 9–12 mm.×0.4 mm. The ova measure 64–75×36–40 μ . The buccal armature of the two species differs. The capsule is smaller in *N. americanus*, and has an irregular border instead of the four ventral hook-like teeth of *A. duodenale*; there is also a pair of semilunar plates. All subsequent description applies to both these parasites.

When feces containing ova are deposited on moist earth the rhabditiform larvæ hatch out in 24 to 48 hours: later they moult twice, developing into filariform larvæ which may remain viable for three to four months. On contact with human skin the latter bore their way into the blood vessels, pass to the right heart and lungs whence they progress via the trachea, œsophagus and stomach to their natural habitat in the duodenum and small intestine; here they mature and breed, egg-laying commencing in about 5 weeks. The worms attach themselves firmly to the mucosa, feeding on blood and may cause local bleeding (especially *A. duodenale*), though the stools generally give a negative test for occult blood. At autopsy œdema of the legs and sacrum are common, and effusions and petechiæ may involve the serous sacs. The heart is dilated and shows marked fatty degeneration, as do also the liver and kidneys. The duodenum and jejunum may present petechial hæmorrhages, especially at points where the worms are attached.

Symptoms.—At onset the larvæ may produce ancylostome dermatitis or ground itch, which clears up within two weeks unless secondary infection has occurred. In heavy infection symptoms may appear within one to two months. These are largely related to the anæmia which is microcytic and hypochromic in type; there is a low colour index, and an increased blood volume. The counts in a severe case would show R.B.C.'s—1,000,000–2,500,000 per c.mm.; hæmoglobin = 10–25 per cent.; colour index = 0.5. Leucocytes are normal or slightly increased in number, and eosinophilia is characteristic. Mild cases may be symptomless, and it is uncommon for the well-fed European to develop anæmia even when severely infected. Anæmia rarely occurs except in patients living on a borderline diet, poor in animal protein and iron-containing foods. Those moderately infected may complain of mental and physical lethargy, hyperacidity, epigastric tenderness, palpitations, and shortness of breath. The really severe case may show a tallow-yellow discoloration of the alæ nasi and forehead, a dry, earthy-coloured skin, pallor of the mucous membranes, mental sluggishness, dilated stomach and epigastric tenderness; earth-eating sometimes occurs and constipation is frequent. Dyspnoea, cough, palpitations, pulsating cervical veins and hæmic murmurs are common; retinal hæmorrhage, œdema of the feet and serous effusions may occur. Hook-worm disease causes great economic loss to the community by lowering the individual's physical and mental capacity for work and predisposing to secondary infections like pneumonia and dysentery. In Europe outbreaks have sometimes occurred in miners.

Diagnosis.—A microcytic, hypochromic anæmia, especially if associated with eosinophilia, should arouse suspicion in a tropical patient, and the stools should be immediately examined for ova, preferably by the Clayton-Lane flotation method.

Prognosis.—The mortality rate is low, even in natives, the chief danger being anæmia, which predisposes to intercurrent disease unless specific treatment be instituted. Hook-worm infection is especially serious in children owing to its effects on their mental and physical development. In the well-fed European the disease rarely produces serious manifestations.

Treatment.—**PROPHYLACTIC.**—This includes the treatment of carriers, the substitution of latrines for promiscuous defæcation, the proper disposal of night soil, the treatment of contaminated ground and the wearing of good shoes and boots. Sanitation in mines must be satisfactory.

CURATIVE.—There are three specific drugs which are widely used in the treatment of ancylostomiasis: (1) tetrachlorethylene; (2) carbon tetrachloride; and (3) oil of chenopodium. Either tetrachlorethylene or carbon tetrachloride can with advantage be combined with oil of chenopodium, and this should be done whenever possible. After saline purgation, the object of which is to get rid of both drug and parasites, the stools should be examined and the number of worms recorded if time permits. In seven to ten days' time the stools are re-examined; if ova have reappeared another course of treatment may be considered advisable.

(1) *Tetrachlorethylene*. Adult dosage 3–4 c.c. This drug is effective against *A. duodenale*, *N. americanus* and *Enterobius vermicularis*. It is the safest and cheapest anthelmintic, and is given in a single dose of 4 c.c., either in gelatine capsule or shaken up with $\frac{1}{2}$ –1 ounce of magnesium sulphate in water; 1 c.c. of oil of chenopodium should be added or administered in a

gelatine capsule. These are given in the early morning on an empty stomach. No food is permitted until the bowels have acted, and magnesium sulphate (4 drachms) should be repeated after three hours if necessary.

(2) *Carbon tetrachloride*. Adult dosage 3 c.c. This drug is of value in thread worm and ascaris infestation, as well as in ancylostomiasis. The drug is given in a dosage of 3 c.c., either in gelatine capsules or in milk or in magnesium sulphate solution. It is administered in the early morning on an empty stomach, and food is withheld until the bowels have been well opened—if necessary with magnesium sulphate. If available it is advantageous to combine this treatment with oil of chenopodium. As a routine, 1.5 c.c. of carbon tetrachloride and 0.5 c.c. of oil of chenopodium are administered in a mixture containing $\frac{1}{2}$ ounce of magnesium sulphate, and the same dose is repeated in one hour's time. If necessary, a saline purge is given three hours later. Carbon tetrachloride when administered in poisonous doses causes a central lobular necrosis of the liver, with fatty degeneration. Clinical evidence of poisoning include vomiting, hepatic pain and tenderness, jaundice, hæmaturia, and temporary anuria. Fatalities have been reported, and it is inadvisable to employ this drug to (1) alcoholics; or (2) patients suffering from calcium deficiency, cirrhosis of the liver, or renal disease. A preliminary course of high protein dietary would probably prevent hepatic necrosis developing in such cases.

(3) *Oil of chenopodium*. Adult dose 1–3 c.c. This drug is effective against ascaris, as well as ancylostomiasis. Its therapeutic action is dependent on the ascaridol content, which is by no means always constant. It is best given in gelatine capsules, or it may be taken in an emulsion or in water mixed with other anthelmintics, such as tetrachlorethylene or carbon tetrachloride. If used alone, the drug may be administered in divided doses, i.e., $\frac{1}{2}$ c.c. half-hourly for two hours, or in a single dose of 2 c.c. followed by a saline purge. Narcosis and other ill effects have followed its administration, and cumulative effects have been noted. Treatment should not be repeated under ten days. In case of poisoning, digitalis and epinephrin have been found useful, but there is no chemical antidote.

The effectiveness of treatment is determined by the disappearance of symptoms, and of ova from the faeces as revealed by later microscopic examinations.

Treatment of anaemia depends on: (1) eradication of the ancylostome infection; (2) a well-balanced diet containing meat, proteins, fruit, vegetable, lipoids and vitamins, and as regards the latter a whole wheat bread is most desirable if obtainable; (3) iron in large dosage; (4) treatment of intercurrent infections, such as malaria. Ground-itch may be treated with an ointment containing zinc oxide and salicylic acid. If there is secondary coecal infection, antiseptic dressings are indicated.

ASCARIASIS

Definition.—An intestinal infection of man with the round worm *Ascaris lumbricoides* (Linnaeus, 1758).

Ætiology.—Adults ♂ 17–25 cm. × 3 mm.; ♀ 20–40 cm. × 5 mm. The eggs are yellow, elliptical, possess a thick outer shell and measure 50–70 × 40–50 μ . Ova passed in human faeces develop in night soil, and

the fertilised eggs, swallowed by man in contaminated water or food, pass into the intestines where the larvæ penetrate the bowel wall and migrate to the lungs, sometimes producing ascaris pneumonia; thence, via the trachea and œsophagus, they reach the intestine (Stewart). Ova appear in the fæces in two to two and a half months.

Symptoms.—During larval migration urticaria, ascaris pneumonia, and, more rarely, ascaris nephritis may occur. Pulmonary complications appear early in the first week and are generally transient in nature. Adult worms may produce symptoms by toxic, reflex or mechanical means. Sensitised individuals occasionally develop rashes such as urticaria and œdema of the face, and in children, gnashing of the teeth, enuresis and convulsions are described. Reflex dyspnoea, abdominal pain and diarrhoea, with or without blood, may occur (ascaris dysentery), while masses of coiled-up worms sometimes produce acute intestinal obstruction. Perforation of the intestine leads to peritonitis or localised abscess from which worms may be discharged. Wandering worms may produce appendicitis or obstruct the pancreatic or bile ducts causing jaundice, or reach the liver producing liver abscess or cholecystitis. They have been known to enter the larynx and cause œdema of the glottis or even to appear in the antrum of Highmore.

Treatment.—Oil of chenopodium ($1\frac{1}{2}$ c.c.) carbon tetrachloride and tetrachlorethylene (3 c.c.) are specific remedies; in combination given as in ancylostomiasis they are particularly efficacious (see Ancylostomiasis). Santonin (3–5 grains) is the stock remedy; it may be given on consecutive or alternate days on three occasions combined with preliminary starvation and followed by castor-oil; in children, where the dosage is proportionately lowered, it may be combined with scammony or castor-oil. Hexylresorcinol in 1 g. doses is also recommended and should be followed by a saline purgative. Worms sometimes take 48 hours to be ejected, and the only index to cure is the permanent disappearance of ova.

TRICHURIASIS

Definition.—An infection of the human intestine with the whip worm *Trichuris trichiura* (Linnæus, 1771), formerly known as *Trichocephalus dispar*.

Ætiology.—Adults, 40–45 mm.; 45–50 mm. Ova are brown, barrel-shaped with terminal knobs and measure $50-54 \times 23$ microns. Man is infected by swallowing the fertilised eggs in food and water; on reaching the cæcum the larvæ are liberated and attach themselves to the mucosa. Occasionally they invade the appendix, colon and terminal ileum.

Symptoms.—Clinical features are generally entirely absent, but reflex symptoms are described in children and occasionally urticaria and eosinophilia are induced. Rarely verminous appendicitis and peritonitis may result, and possibly cæcal lesions may open up the way for other infections.

Treatment.—Thymol and oil of chenopodium may be effective, but worms are often difficult to eradicate.

ENTEROBIASIS

Definition.—Infection by the thread or pin worm *Enterobius vermicularis* (Linnæus, 1758), formerly known as *Oxyuris vermicularis*. Adults

♂ 3-5 mm.; ♀ 10 mm. \times 0.6 mm. The ova measure $50 \times 20 \mu$, and are thin-shelled, colourless, plano-convex and contain coiled embryos; they are rarely found in the faeces, being mainly liberated in the perianal region from migrating gravid female worms at night, after the patient has gone to bed. The maximum length of the life cycle is 30 days, long-standing enterobiasis resulting from autoinfection via the infected fingers of the patient.

Symptoms.—The worms inhabit the colon, and when the patient is warm in bed at night may produce great discomfort and itching by migrating out through the anus. Eczema and pruritus ani may result causing sleeplessness and neurasthenia. Sexual disorders, vesical irritability, frequent micturition, prolapsus ani and mucoid secretion may be observed, also in young girls vaginal discharge. Catarrhal appendicitis sometimes occurs, and worms may wander into the stomach.

Diagnosis.—Eggs are best demonstrated by swabs made from the perianal skin. Inspection of the anal region at night immediately when itching commences may reveal the gravid female worms outside the anal canal before they have had time to retreat to the rectum.

Treatment.—The secret of successful treatment is the prevention of auto-infection. This is best done by the most scrupulous care of the hands and nails which may become contaminated (1) by scratching in the anal region, especially during sleep, (2) when completing the anal toilet with sanitary paper, or (3) from infected clothes. The nails should be kept short, and the hands well washed and scrubbed with carbolic soap immediately on waking, after defaecation, and every time there has been possible contact with infected material or clothing. Bathing drawers or pyjamas should be worn at night and sterilised each day, and infected children should occupy separate beds. Enemas of 4-8 fl. ozs. of hypertonic saline solution should be injected immediately the anal irritation commences, for at this time the worms are accessible and can be washed out from the rectum (Macarthur). The process should be repeated each night whenever anal irritability recurs. If re-infection be prevented this measure alone will generally result in cure.

Gentian violet appears to exert a specific lethal effect on the adult worms. Wright has recently advocated special keratin-coated tablets of this drug, the adult dose being 1 grain thrice daily before meals for eight days; this course is repeated after a clear interval of seven days. Toxic features include anorexia, nausea, abdominal cramp and vomiting. Over 90 per cent. cure is claimed.

N. HAMILTON FAIRLEY.

D. DISEASES DUE TO INJURIOUS ARTHROPODS

TICK BITES

Apart from relapsing fever, tularæmia and certain typhus-like fevers the bites of several species of ticks, including *Dermacentor andersoni*, *D. venustus*, *Hamophysalis punctata*, *Ixodes ricinus* and *I. holocyclus*, may give rise to paralysis in man. Cases have been recorded from Australia, South Africa and the United States. The incubation period varies from several hours

to six days ; the bites, which are generally situated on the nape of the neck, are painful and cedematous, and the disease, which is afebrile, may be fatal, especially in children. The paralysis is of lower motor neuron type resembling that seen in infantile paralysis, and develops first in the legs and later in the arms and neck. In removing ticks the parasite should not be forcibly extracted until paraffin or carbolised oil has been applied, as this causes withdrawal of the head and so prevents it being broken.

MITES

Apart from scabies, camel itch and copra itch, all of which are caused by different species of mites, several typhus-like fevers, including tsutsugamushi fever, are transmitted by these minute acarines. The harvest mites of temperate climates cause considerable itching and skin erythema, which comes on 12 hours after exposure and increases for 36 hours, sometimes persisting for several days. It may be prevented by anti-mite fluids, such as dibutyl or dimethyl phthalate applied to the socks and clothing ; it is treated by washing the legs with benzine, green soap or salt solution, while the itchiness may be combated, as in flea-bite, by the use of 1 in 10 carbolic lotion or an ointment composed of acid. carbol. (gr. 10), menthol (gr. 5), zinc oxide (gr. 60 and adip. præp. (1 oz.) (Roxburgh) may be used. Larval mites of the family *Trombididae* are known to cause skin eruptions in various parts of the tropics. One, in the West Indies, produces red mite dermatitis (*bête rouge*), the little crimson spot in the middle of the itchy papule being diagnostic ; another, in Mexico, has a predilection for the skin of the eyelids, prepuce and axilla. Owing to the fact that many adult mites have never been identified, species names are not generally available for the larvæ. Scrub-itch commonly results from the bites of trombiculid larval mites, such as *T. minor* in Australia and New Guinea (*vide* Tsutsugamushi Disease, p. 296).

TONGUE WORMS

The adults, which are degenerated, segmented arachnids superficially resembling tape-worms, live in the lungs or nostrils of certain carnivora or ophidia, and deposit their eggs on vegetation ; when these are eaten the larvæ encyst in the viscera of the intermediate host. Only two species have been reported in man, *Linguatula serrata*, which occurs in parts of Europe and Brazil, the larvæ encysting harmlessly in the human liver, and *Porocephalus armillatus*, which encysts in the mesentery, liver and lungs. The infection is not uncommon in the Belgian Congo. Pulmonary symptoms have been reported, and sometimes the larval forms wander free in the peritoneal cavity. If the cysts have become calcified they may be detected by X-ray examination (Low and Cordiner) ; otherwise the disease is only recognised at autopsy. No treatment is known.

INSECT BITES

Apart from specific disease transmission, bites from mosquitoes, biting flies, midges, lice, fleas, bugs, bees, ants, wasps and hornets may cause considerable inconvenience to man and occasionally result in local sepsis or

septicæmia, both of which may end fatally. Mosquito bites occasionally give rise to streptococcal septicæmia, and those of horse flies to anthrax.

Locally, insect venom may have hæmolytic, neurotoxic or irritant effects producing limited inflammation, or the dermal whealing which results may have an anaphylactoid origin dependent on previous sensitisation, as Boycott has proved for midge bites. The stings of bees, wasps and hornets are invariably painful, and in certain situations like the tongue and fauces may lead to respiratory obstruction, or in the larynx to death from œdema of the glottis. Anaphylaxis may follow bee or wasp stings in a sensitised individual. Such patients may suffer from profound vasomotor collapse, become comatose and die in 20 minutes. In a case of wasp sting seen by us the patient, who gave a history of having been stung on the scalp six years previously, was again stung on the third right finger; a wheal about 2 cm. in diameter rapidly appeared with surrounding erythema, and within five minutes the patient developed headache, lachrymation and injection of the conjunctivæ. Giddiness, nausea, severe vomiting, rapid low tension pulse with vasomotor collapse, generalised urticaria, especially involving the arms and neck, and respiratory distress followed; three hours later the general condition was greatly improved, but next day there was a large, puffy, painless swelling involving the subcutaneous tissues of the whole hand. The early and late local effects closely resembled those observed in the immediate and delayed intradermal reactions for hypersensitiveness to helminthic protein.

Treatment.—Mosquito, midge and fly bites may to some extent be prevented by the use of essential oils such as citronella applied to the clothing. They should be treated by the immediate application of iodine, the subsequent itching being relieved by a 1 in 20 watery solution of carbolic or a 1 per cent. alcoholic solution of menthol. In bee and wasp stings, the sting should be carefully lifted or scraped out, as pressure expels the contents of the poison sac. Ammonia, alkaline soap or methylene-blue may be applied locally for the acid bee stings, and vinegar for the alkaline wasp stings. Adrenaline (min. 10 of 1 in 1000 solution) should be immediately injected subcutaneously whenever anaphylactic symptoms develop. Sepsis is treated along the usual lines.

MYIASIS

Definition.—An invasion of the tissues by larvæ of dipterous insects.

Ætiology.—Many flies deposit their eggs or larvæ in decomposing discharges, and in the tropics wounds should always be protected as well as natural orifices discharging pus or fetid material. Larvæ of special flies may develop in the nasal cavities, the ear, vagina, urethra, skin or in the intestine, and the fly *Wohlfartia magnifica* may deposit its eggs in the conjunctival sac with serious consequences. Two chief varieties are distinguishable—the dermal and the intestinal.

THE SCREW WORM (*Cochliomyia macellaria*).—This fly, common in most of tropical and subtropical America, measures 9 to 10 mm. in length and is distinguished from the ordinary blue-bottle by the three black, linear, dorsal marks on its thorax. It lays its eggs upon foul wounds, the larvæ hatching in a few hours, and when mature measuring 2 to 3 inches in length. Superficially the larva resembles a screw, being formed of twelve segments, each with a series of spines—it burrows into and feeds on the tissues, causing great

destruction locally. When the nose is affected the larvæ often pass into the accessory sinuses, bore their way through the bones and even penetrate the skull, causing death by purulent meningitis. The vagina and ear may also be attacked and the middle ear destroyed.

Treatment.—**PROPHYLACTIC.**—This consists essentially in covering all wounds and discharging orifices, and avoiding sleeping in the open. Larvæ can be removed from wounds by ordinary antiseptic methods, and for nasal cases injection of chloroform, carbolic acid or turpentine may be used. Accessory sinuses may need to be opened.

THE MOSQUITO WORM (Ver macaque, beef worm) (*Dermatobia cyaniventris*).—This fly, common in Central America and adjacent parts of South America, measures 14 to 16 mm. in length, has a yellow head with brown eyes, a greyish thorax and dark metallic-blue abdomen. The eggs somehow become glued to the under surface of mosquitoes (particularly of the genus *Janthinosoma*), biting flies and even ticks, and in this fashion the larvæ are conveyed to the human skin where they invade the tissues via the puncture wound. A boil or warble results, containing a central opening through which the maggot breathes, discharges black excreta, and later escapes to the ground where it develops into a chrysalis and finally a fly. Cattle are also affected. Hadwen and Bruce have described a remarkable anaphylactic condition in oxen and sheep infected with larvæ of warble flies (*Hypoderma bovis*, *H. lineatum* and *Cestrus ovis*) characterised by dyspnoea, salivation, lachrymation, incontinent sphincters, vasomotor collapse, cyanosis and even death. This may be experimentally induced by injections of larval protein extracts or may result from natural trauma during life. Similar clinical features have not yet been recognised in man, though they probably occur.

Treatment.—Natives kill the larvæ with tobacco juice. The opening should be enlarged with a bistoury and the maggot removed with forceps; the cavity soon heals if treated antiseptically.

VER DU CAYOR OR TUMBU DISEASE.—This disease, common in Central and West Africa, is due to the larvæ of the Tumbu fly, *Cordylobia anthropophaga*, which is 8.5 to 11.5 mm. long, yellowish in colour, with black abdominal spots. The eggs are laid on the ground or clothing, and the emerging larvæ bore their way into the tissues by means of mouth-hooks. The first symptom is a pricking sensation, followed by the appearance of a boil or warble which commonly affects the buttocks, thighs and scalp of children, and often becomes inflamed. The larva takes about a fortnight to mature and then escapes via the central hole through which its fæces were previously excreted. Sometimes the cavity suppurates. Blacklock and Gordon demonstrated an acquired local skin immunity against cordylobia larvæ in guinea-pigs subjected to previous infection.

Treatment.—The aperture is enlarged if necessary, the maggot squeezed out, and the cavity treated antiseptically.

THE CONGO FLOOR MAGGOT.—The adult fly, *Auchmeromyia luteola*, is found throughout tropical Africa; it deposits its eggs on the floors of huts and outhouses, and when the larvæ have hatched out they suck the blood of people sleeping on the ground without causing pain. The larvæ crawl actively, are 15 mm. long and consist of 11 segments. The adult is orange-yellow in colour, with longitudinal dorsal stripes on the thorax, and measures 10 to 12 mm. in length. Prophylaxis consists in sleeping on raised beds.

INTESTINAL MYIASIS.—Fly larvæ are common in human faeces ; generally they are deposited after defæcation, but sometimes they originate from the intestine, the eggs being swallowed by man in food. Many species have been described, the genera *Sarcophaga*, *Fannia*, *Apiocaela* and *Anthomyia* furnishing the majority of examples. *Fannia canicularis* accounts for most cases in Europe. Gastro-intestinal symptoms may be mild or severe and include malaise, vomiting, diarrhœa and severe griping. General toxic features may include fever, rigors, headache, thirst and vertigo ; even convulsions have been described. The bile ducts may also be implicated.

Treatment.—Castor-oil is generally sufficient, but thymol, filix mas, santonin and turpentine have also been recommended.

SPIDERS

Though spiders (Araneæ) generally possess poison glands and inject venom into their prey, only a few species, mostly of the genus *Latrodectus*, are dangerous to man. Experimentally such venoms may slow the pulse and respiration, and produce tetanoid-like spasms and bronchial contraction in guinea-pigs. The red-backed spiders *L. mactans* in America, and *L. hasseltii* in New Zealand and Australia, and *L. geometricus*, *L. concinnus* and *L. indistinctus* in South Africa, where their colloquial name is "knoppie spider," produce local inflammation, œdema and numbness at the site of the bite as well as neurotoxic manifestations. In Peru the "pruning spider," *Glyptocranium gasteracanthoides*, causes local gangrene, hæmaturia and neurotoxic symptoms. Kobert noted oxyhæmoglobin and methæmoglobin in the urine of persons bitten by the "cross spider," *Epcira diadema*, and Sachs found in its venom a powerful hæmolysin. Probably many other spider venoms, like zootoxins generally, exert agglutinative, hæmolytic and neurotoxic effects. The tarantulas, on the other hand, give rise only to minor symptoms, though any spider with an effective biting mechanism may produce secondary bacterial infection. If seen early, treatment consists in immediate ligature, incision and suction, or washing out the wound with permanganate solution. Antiserum, if available, is effective. Morphine may be necessary to relieve pain, and injections of calcium gluconate (10 c.c. of a 10 per cent. solution) for laryngeal and muscular spasm. Intravenous saline and dextrose solution, and injections of nikethamide (coramine) and pituitary (posterior lobe) extract assist circulatory failure.

CENTIPEDES

The Scolopendridæ possess poison glands which discharge at the apices of a pair of specialised claws taking the place of the first pair of legs. The small centipede gives rise only to local manifestations associated perhaps with an erysipelas-like eruption, but the tropical species, *Scolopendra gigantea*, may cause around the punctures local necrosis and lymphangitis ; headache, vomiting, fever, coma, and in children even death may follow. Treatment is similar to that of spider bites. Strong ammonia applied locally is useful.

SCORPIONS

Scorpions possess paired poison glands in the post-anal segment of the spined tail; this is thrust forward into its prey which is held in position by the formidable pedipalps. Scorpions in the tropics not infrequently kill children, and occasionally adults, and several species of the genus *Buthus* and *Centruroides*, as well as *Euscorpheus italicus*, *Tityus bahiensis* and *Centruroides exilicauda*, etc., are much feared. The bite is most painful, and toxic symptoms may include fever, sweating, vomiting, diarrhoea, muscular cramps, trismus, stiffness of the neck, muscular paresis, respiratory failure and coma. Secondary bacterial infection is not uncommon. Acute abdominal symptoms due to hæmorrhagic pancreatitis have been recorded in Trinidad, and pancreatic cyst is regarded as one of the complications of scorpion poisoning there. Local treatment may be instituted as for spider bite, and the immediate application of strong ammonia or a local injection of cocaine and adrenaline relieves the pain. The intravenous injection of specific antivenene (5 c.c. for children and 10 c.c. for an adult), prepared by inoculating scorpion venom into horses, has greatly lowered the mortality rate amongst children in Egypt and South America.

N. HAMILTON FAIRLEY.

E. DISEASES DUE TO SNAKES AND POISONOUS FISHES

SNAKES

Ophidiiasis or snake poisoning results from the inoculation of venom by snakes of the families colubridæ or viperidæ; non-poisonous species occasionally cause death through septic infection following their bites.

Ætiology.—Snakes are carnivorous, and Alcock and Rogers showed that even non-poisonous species may have poisonous saliva. The venom is simply a specialised secretion of the parotid (poison gland) utilised in killing and digesting prey, while the fangs are modified maxillary teeth anteriorly grooved in the colubridæ, and completely canalised in the viperidæ. The biting mechanism is vastly superior in the vipers since the fangs are longer, and capable of considerable forward rotation, whereas in the colubridæ they are generally shorter and less mobile. In biting, the snake strikes with great speed, opens the jaws, rotates forward the fangs, snaps the jaws together and ejects its venom from the poison gland via the duct and fang into the tissues in one almost instantaneous movement. The vipers withdraw immediately after biting. The colubridæ often hang on to the bitten part and may need to be forcibly evulsed: to inject venom effectively they must have the lower jaw fixed, and though their venoms are more poisonous the yield is, as a rule, considerably less than that of the vipers. The toxic action of venoms is mainly dependent on (a) proteolytic enzymes, (b) phosphatidases

and (c) neurotoxins. The proteolytic enzymes, so well represented in viperine venoms, digest the tissues and damage the vascular endothelium (hæmorrhagin), leading to the escape of blood and the liberation of histamine which causes extensive local œdema and gives rise to symptoms of cardio-vascular failure (Kellaway). The coagulant properties of venoms are due either to a direct coagulation of the fibrin by the venom or to the conversion of prothrombin into thrombin (Eagles). The phosphatidases cause hæmolysis and also directly affect the heart and circulation; the acceleration of venom hæmolysis by lecithin is attributed to the transformation of lecithin into lysolecithin, which is itself actively hæmolytic. The neurotoxin formed in colubrine venoms has a strong peripheral effect, paralysing the sensory, proprioceptive and motor nerve endings. Paresis of the musculature is due to the curare-like action on the motor endings and a further direct action on the muscle itself (Kellaway).

Pathology.—In colubrine bites there is a congestive mode of death from peripheral respiratory failure, associated with fluid blood, a dilated right heart, and congestion and œdema around the fang puncture. In fatal viperine bites there is hæmorrhage, thrombosis and digestion of tissue locally, associated with a spreading gelatinous œdema resembling "red currant jelly," which sometimes involves the subcutaneous tissue of the whole limb; multiple hæmorrhages are found in the viscera, serous membranes, etc. Ante-mortem clotting is present in small animals, but not in man where the blood is fluid unless, as rarely happens, the fangs enter a vein: death results from cardiac failure, peripheral circulatory failure, secondary hæmorrhage, or septic infection and local gangrene.

Symptoms.—The clinical picture depends on the quantity and quality of the venom injected. Symptoms appear generally within ten minutes to two hours after the bite, nausea, faintness and vomiting being characteristic early manifestations. Cardio-vascular shock follows both colubrine and viperine bites; parietic features predominate in the former, and general hæmorrhagic manifestations in the latter. In colubrine bites the fang marks are not always visible, and pain and local swelling are minimal; these features, however, are marked in the case of viper bites, which show in addition much hæmorrhagic oozing. Histamine shock accounts for the cold extremities, blanched, white skin, low blood pressure, vomiting, rapid thready pulse and extreme prostration. Psychical shock is sometimes an added factor, and may produce a somewhat similar picture in terrified natives bitten by non-poisonous snakes. In the earlier stages in colubrine bites the muscular weakness, ataxic gait and blurred speech may produce a picture simulating alcoholism, and diplopia, ptosis and blunting of sensation are not infrequently added; later there is inability to swallow, the tongue appears swollen, saliva dribbles from the mouth, the breathing, which was at first stimulated, becomes shallow and slow, and in fatal cases cyanosis, coma and convulsions of asphyxial origin ensue; the respirations may become costal in type and death occurs from peripheral respiratory failure. Hæmorrhagic extravasations (viperidæ) may lead to cutaneous petechiæ, epistaxis, hæmoptysis, hæmatemesis, hæmaturia and mæna. In the early stages the gums may ooze blood and the urine contain red corpuscles.

Complications.—Blunting of the cough reflex and paresis of the muscles of deglutition may be followed by insufflation pneumonia. After krait bites

the anterior-horn cells of the cord may fail to recover or an acute ascending paralysis has been recorded some ten days later. With viperine poisoning, local suppuration and gangrene sometimes necessitate amputation.

Course.—Death may occur within 20 minutes or many days later from complications. As a rule colubrine cases surviving for three days recover.

Diagnosis.—Generally this is not difficult, but cases may need to be differentiated from alcoholism and the bites of non-venomous snakes and scorpions. The grooved or canalised anterior fangs in the upper jaw make identification of a poisonous snake easy.

Prognosis.—This depends on the amount of venom injected, the efficacy of local treatment and the availability of specific antivenene. Even with really deadly snakes, factors such as clothing, inefficient biting or a poor venom yield may prevent a lethal dose being injected, and this fact accounts for many extravagant claims regarding the value of weird cures. Most first-aid measures are useless since the ligature is applied ineffectively or too late, and once a lethal dose of venom has been absorbed into the circulation, antivenene given intravenously is the only measure that will save life.

Treatment.—**PROPHYLACTIC.**—Snakes bite man more often by accident than design, and in snake country a little knowledge and common sense regarding the natural habits of the ophidia, the use of lanterns in walking along roads at night and the wearing of strong boots and leggings would greatly lessen the incidence of snake bite. Every second case is bitten below the knee.

CURATIVE.—Only two methods of treatment are of recognised value after a lethal dose of venom has been injected into the tissues: (1) Immediate ligature which delays absorption of venom, followed by such local measures as incision, excision, suction, or the injection of chemicals, the object of which is to remove or destroy inoculated venom before a lethal dose can be absorbed; (2) the intravenous injection of specific antivenene. By temporarily prolonging life, effective ligature may enable antivenene to be given in otherwise fatal cases.

Local Measures.—In sheep bitten by the tiger snake (*Notechis scutatus*) the absorption time of a lethal dose proved to be only two minutes (Fairley), so to be effective a ligature must be in position at the earliest possible moment. Pressure must be applied over a single bone proximal to the heart, i.e. over the femur in foot and leg bites, and over the humerus in bites on the hand and forearm; in finger and toe bites a boot lace may also be tied at the base of the implicated digit. Complete stasis of the circulation has to be attained as judged by blanching of the nails and failure of incisions to bleed. Thick rubber tubing ($\frac{3}{8}$ -inch) is an ideal tourniquet, but in the field, strips of clothing, loosely knotted and twisted with a stick, are effective, and every 20 minutes the tourniquet may be loosened for 30 seconds to flush the limb with blood. After ligature the skin should always be wiped clean or washed, otherwise incision and scarification may lead to absorption of venom deposited and dried there (Ferguson). Scarification with or without the application of permanganate crystals is not effective, and mere incision is of doubtful value; it should be combined with suction either by the mouth or preferably with a breast pump or a Bier's suction glass. Excision of the bitten area and washing with permanganate solution, followed by mechanical suction is the best local treatment, and is the only one available where ligature is inapplicable as in body bites. Polyvalent antivenenes are now available for cobra and Russell's

viper in India, for the viperidæ and colubridæ of Africa, for the more deadly snakes of South America and for the erotalinæ of the United States. In Australia there is a monovalent antivenene for the tiger snake. The dosage varies, but antivenene must always be given intravenously as early as possible, and in colubrine bite is effective up to approximately two-thirds of the death time (Aeton and Knowles). No case is too ill to receive it and even the most severely paralysed cases may recover; such patients must be carefully watched, as paralysis may reappear and further injections be necessary. In viperine bites it is less effective, and must be given in full dosage at the earliest moment. Infiltration of the tissues with antivenene in the vicinity of the bite may be useful (FitzSimmons). *General Measures*.—Patients must be kept warm and at rest. Black coffee and sal volatile may be given early, and injections of eortin, adrenaline or pituitary (posterior lobe) extract and of reconstituted plasma, followed by isotonic dextrose (5 per cent.), administered for circulatory shock. Nikethamide (coramine) has value as a respiratory and circulatory stimulant. Artificial respiration may prolong life, and it is important in cases with pharyngeal paresis to swab out the throat and keep the head low when the patient vomits; food should be withheld, and, if necessary, fluid given through a stomach-tube.

POISONOUS FISHES

In tropical waters casualties from poisonous fish are not infrequent. The effects of jelly-fish stings vary with different species; many are harmless, others produce local features such as urticaria, œdema, marked itching, burning and erythema, sometimes followed by vesicular dermatitis or actual sloughing and ulceration. Systemic symptoms may follow rapidly and include lachrymation, coryza, muscular pains, constriction of the chest, dyspnoea and cardiovascular shock. Deaths have been reported.

Fish of the genus *Muraena* bite with their powerful, grooved teeth down which poison from the venom sac enters the tissues; many harmful species are known, and their venom may have a depressant action on both the cardiac and nervous systems.

In other fish, such as the sting-rays, there are barbs in the dorsal fin or elsewhere connected with poison glands and these may produce not only severe inflammation locally, but neurotoxic features. Tetanus organisms may simultaneously be inoculated. Certain species of *Trachinus*, such as *T. draco* found in the Mediterranean, and of *Scorpena*, such as *S. scorpa* inhabiting tropical waters, are particularly dangerous, causing excruciating pain and local irritation, œdema, paralysis of the part, collapse, dyspnoea, delirium and even death within 24 hours. Septic infection may follow. Local treatment as for snake bite should be adopted. Infiltration of the tissues with procaine hydrochloride (novocaine) (2 per cent.) is often advisable for relief of pain, and morphine also may prove necessary.

N. HAMILTON FAIRLEY.

SECTION IV

DISEASES DUE TO PHYSICAL AND CHEMICAL AGENTS

CAISSON DISEASE

Synonyms.—Compressed Air Illness ; Divers' Paralysis.

Definition.—Caisson disease is the name given to a series of phenomena which may result in any living animal upon return to a normal atmospheric pressure after exposure to an air pressure which must exceed 18lb. to the square inch above mean atmospheric pressure. These phenomena occur the more frequently and severely the greater the air pressure, and in direct proportion to the length of time of exposure to the high air pressure, and the more rapid the return to a normal atmospheric pressure. They are caused by the saturation of the living tissues with nitrogen at high atmospheric pressure which, on too rapid return to lower atmospheric pressures, boils within the tissues, and this liberation of bubbles of nitrogen causes tissue disruption and destruction on the one hand, and gas emboli on the other. The major capacity of fat to hold nitrogen in solution causes the liberation of nitrogen bubbles to occur most readily in the fatty tissues, and this occurs more easily in those parts of the body where the blood supply is less abundant, and therefore the rapid return of the excess of nitrogen to the atmosphere by solution in the blood stream less easy. For these reasons the white matter of the nervous system, composed as it is of fatty substance, and particularly those parts of it which are less liberally supplied with blood, such as the white matter of the lower dorsal spinal cord, is the most common site of gas liberation. The joints and also their surrounding structures, which are lowly vascularised, are also common sites of the lesions, as are also the subcutaneous tissues of fat subjects, on account of the high solubility of nitrogen in the fat.

These phenomena occur only upon decompression, and are always preventable if adequate means be adopted (1) to limit the time of exposure to very high atmospheric pressures, so that high degrees of tissue saturation with nitrogen shall not occur, and (2) to regulate the return to normal atmospheric pressure by graduated decompression, in such a way as to prevent boiling of nitrogen in the tissues. They are curable, after they have appeared, by immediate recompression followed by very gradual decompression. Exposure of the living animal to very high atmospheric pressures may be associated with most serious and usually fatal results, which occur before decompression, and which are due to over-saturation of the tissues with oxygen, death resulting from oxygen poisoning.

Etiology.—This disease made its appearance in the middle of the nineteenth century, when the invention of Siebe's diving dress and of subaqueous chambers made it possible for subaquatic engineering and marine salvage

to be performed under high atmospheric pressures. The men work in a pressure of air, which just exceeds the hydrostatic pressure of that depth of water which extends from the working position to the surface, and the pressure is produced and maintained by pumps and regulating apparatus. Workmen reach the working face of the caisson by passing from the normal atmosphere through a series of chambers with airtight doors, in which the air pressure is raised by rapid stages, until the high pressure of the working face is reached. They leave through the same chambers, the air pressure being lowered for some space of time in each as they pass through. This process is termed "compression" and "decompression," or "locking in and out." The diver is compressed as he slowly descends by an increasing air pressure from his pump, and is decompressed as he ascends much more slowly, this compression being regulated by an automatic valve in his helmet which retains the air pressure until it exceeds that of the water pressure outside. Caissons are worked under a much lower pressure than that at which divers can work; but the working shifts are much longer, whereas the diver at great depths remains down only a very short time. Roughly speaking, each 33 feet of water produces a pressure of 15 lb. to the square inch ($5\frac{1}{2}$ fathoms). Caissons are usually worked at a pressure of below 35 lb. and in 6- to 8-hourly shifts, but they have been successfully worked at a pressure of 45 lb. with 2-hourly shifts, and at 50 lb. with 1-hourly shifts. Divers frequently work at 20 fathoms (53 lb.), and the record depth and pressure reached has been 210 feet (95 lb.).

During compression no trouble is experienced beyond discomfort in the ears and rarely perforation of the membrane tympani, from disparity of air pressure in the middle ear. This the workmen avoid by opening the Eustachian tubes with an act of swallowing or yawning; but it must be remembered that no person suffering from Eustachian catarrh should be allowed to enter the air locks. Under high atmospheric pressures combustion proceeds more readily, a candle when lighted burns away furiously, and a pipe bursts into flame with each draw. The workmen find that they can work more easily and with less fatigue.

The symptoms of the disease become manifest upon return to a lower atmospheric pressure, and directly in proportion to the suddenness of return to such pressure. If the return to a normal atmospheric pressure from a high and prolonged pressure be sudden, there may be a liberal escape of bubbles of nitrogen gas in the blood and in the tissues. The presence of the nitrogen may sometimes be felt as gas crackling underneath the skin or subcutaneous emphysema.

When the return to a normal atmospheric pressure is more gradual, the nitrogen may have time to escape from the blood and from most of the tissues by diffusion through the lungs, but in those tissues which are relatively less vascular, and from which, for that reason, interchange of gases by means of the blood stream is slow, or in these tissues in which nitrogen is especially soluble, such as the fats and myelin of the nervous system, the nitrogen is liable to escape in the form of bubbles, and to the mechanical effects upon the tissues in which the hoiling of the nitrogen occurs, the symptoms of caisson disease are due.

That part of the nervous system which is least vascular, namely the four lower dorsal segments of the spinal cord, is the most common region

for the lesions to occur, while the joints and peripheral nerve trunks are often affected.

Massive escape of gas may occur into the blood stream, and the heart has been found distended with gas after death in rapidly fatal cases. A similar escape of gas into the intestines may produce severe and even fatal abdominal distension. It is doubtless one of the causes of the abdominal pain, nausea and vomiting which are common symptoms of compressed air sickness.

The liberation of these gases, and therefore the occurrence of the compressed air disease, depends directly upon these factors—(1) the amount of pressure to which the living animal is exposed; (2) the length of time of exposure to the high pressure; and (3) the rapidity with which a return is made from the high pressure to normal atmospheric pressure. For example, the malady never occurs after short exposures, such as 15 minutes at a pressure of 45 lb., or 2 minutes at a pressure of 75 lb., even though decompression be as rapid as possible, for these periods are too short to allow of nitrogen saturation of the tissues. It is for this reason that compressed air sickness is so much less common in divers, who for the most part work for very short times only at high pressures, and so much more common in caisson workers, who work for many hours at a stretch at a pressure of from 30 to 40 lb.

There is one other factor which must be carefully borne in mind, and that is the amount of fat present in the body, which, from its nitrogen dissolving qualities, greatly increases the tendency to nitrogen boiling within the tissues if it be present in large amount. It has been shown experimentally that fat animals succumb to the disease while lean ones escape, and experience has shown the necessity of excluding fat workmen on account of their liability to the malady.

The disease is obviously always preventable, firstly by shortening the periods of exposure according to the height of the pressure so as to obviate nitrogen saturation; and secondly by arranging that such a graduated and prolonged return to normal pressure be made, as will prevent any possibility of nitrogen boiling, the slow return to normal pressure allowing of the nitrogen desaturation of the tissues without bubble formation.

It is quite safe, and does not produce any ill effects whatever for a man to breathe pure oxygen for as many as 6 hours at a time. This has been proved by the use of the Siebe-Gorman life-saving dress for rescue work from choke damp in mines. Beyond a certain limit of pressure, however, oxygen becomes poisonous. Highly compressed air causes rapid toxic effects in proportion to the partial pressure of the oxygen. It tends to cause direct death of the tissues. At lower partial pressures it has a convulsant effect, and at still lower pressures produces congestion of the tissues and especially of the lungs, which may present consolidation and all the signs of acute pneumonia, however slowly and carefully decompression has been accomplished. The limit of safety so far as oxygen poisoning is concerned is 10 atmospheres, or 300 feet of water. Neither divers nor caisson workers ever work at anything like so high a pressure.

The essential feature on post-mortem examination is the presence of bubbles of nitrogen in the tissues or bulky collections of nitrogen within the organs, as in the heart or in the intestines, and the results of the associated tissue disruption and air emboli. When it is considered that the mass of

blood constitutes about 5 per cent. of that of the whole body, and that the capacity of the tissues in a thin subject is thirty-five times that of the blood, the ratio being much higher in a fat subject, since fat will dissolve five times as much nitrogen as will any other tissue, the presence of bubbles in the tissues, and especially in the fatty tissues, will readily be understood.

The bubbles form first in the venous blood and in the fatty tissues, where they grow by accretion and cause tearing of the tissues, while air emboli and subsequent necrosis are common. Hundreds of bubbles have been counted in the spinal cord, and these are much more numerous in the white than in the grey matter. Collections of nitrogen may be found in the subcutaneous tissues, and may cause palpable crackling. Bubbles of gas are not uncommonly found in the liver cells. Occasionally similar lesions are found in the brain or in the eye, and in fact may occur in any of the tissues. In every fatal case which has been adequately examined patches of necrosis in the dorsal region of the spinal cord, with the usual secondary degenerations, have been found.

Symptoms.—The symptoms may be first manifest during the process of decompression, when the latter is rapid, and from a high pressure. More often the signs of the malady appear soon after a normal pressure is reached, while not infrequently they do not present themselves until an hour or more has elapsed. In slight cases headache, giddiness, diplopia and faintness may occur, and these symptoms pass off soon and leave no trouble. Severe and important symptoms occur in the following order of frequency: (1) pain in the extremities or trunk, commonly called by the workmen "the bends" from the position in which the painful limbs are held; (2) pain in the epigastrium, sometimes accompanied by nausea, vomiting and abdominal distension; (3) paraplegic paralysis which usually involves motor, sensory and sphincter functions, and extends as high as the ninth dorsal segmental level; (4) headache, vertigo and coma; (5) sudden death; (6) hemiplegia or monoplegia of cerebral origin.

The pain in the limbs is of a neuralgic character and is referred to the joints, which are kept in the semiflexed position, any attempt to straighten them causing great pain. The pain may come on gradually, or suddenly, and may be slight and transient, or severe and persistent. It is often intolerable. The knees, ankles and hips are the most frequently affected; but sometimes the joints of the upper extremities, or of the back and especially of the lumbar region, may be affected. Epigastric pain is common, and unless quickly relieved by recompression is followed by nausea and vomiting.

The paraplegia usually has its upper limit in the lower dorsal, but it may reach the cervical region and involve the arms. It comes on rapidly, and involves motor, sensory and sphincter functions. It may be of any degree of severity from a slight and transient effect to a complete and permanent loss of the functions of the spinal cord. The paraplegia occurs with increasing frequency and completeness in proportion to the degree of pressure and the length of exposure to its influence. It occurred in 61 per cent. of 119 cases in the St. Louis bridge caissons, which were worked at plus 50 lb. of pressure, and among these there were 14 deaths. There is no general relation between the pain and the paralysis, as either may occur without the other, and it seems, therefore, that the pain is due to a peripheral lesion and not to the lesions of the spinal cord.

Course and Prognosis.—The duration of the attack may vary within very wide limits. The severity of the initial symptoms, and the immediate application of appropriate treatment, are the all-important modifying factors in the prognosis. The attack may last for a few hours only, or it may continue for days. The paralysis may recover in a few days, or it may last for months and may never recover. Death occurs only in cases which have severe initial symptoms, and except when occasioned by complications such as cystitis and bed-sores it usually takes place shortly after the attack.

Treatment.—**PROPHYLACTIC.**—Since the malady is due entirely to nitrogen saturation of the tissues, and the subsequent escape from solution of this gas into the tissues during a too rapid return to normal pressures, it follows that the malady can always be prevented by adopting suitable period lengths for compression. In the first place, the malady never arises from compressions below plus 18 lb. to the square inch, or roughly 40 feet of water, and those who work at such a pressure may do so for long hours and return to a normal pressure rapidly, and without any risk. At higher pressures the working shifts must be shortened as the pressure gets higher. The shifts should be not longer than 6 to 8 hours at a pressure of 30 to 35 lb., or 3 atmospheres; 2 to 3 hours at a pressure of 45 lb., and 1 hour only at a pressure of 50 lb. At higher pressures than this, which are only encountered by divers, a few minutes' exposure is allowed only.

Compressed air sickness never occurs if the return to the normal atmospheric pressure be sufficiently slow. Animals can be exposed to very high pressures, short of those causing oxygen poisoning, with impunity, provided they be decompressed slowly enough. This decompression is carried out in the case of the diver by raising him to various levels in stages, and letting him remain at each stage a longer and a longer period as the surface is approached. In the case of caisson workers a series of air-locked chambers is provided in which the air pressure is lowered in stages, the men remaining longer and longer at each stage as they approach the normal pressure. The important fact in connection with decompression is that the absolute pressure can always be halved forthwith without any risk. In the first air lock on leaving the working face of a caisson, for example, the pressure is at once reduced to one-half that of the working face, and in the remaining air locks the pressure is reduced by stages until zero is reached.

Leonard Hill has shown experimentally that it is always safe to lower the pressure to plus 20 lb. by gradual decompression during the space of 10 minutes, then to wait at that pressure for 2 hours, and then bring the pressure to zero by gradual reduction in 10 minutes. The Admiralty rules for divers require that a diver working, say at 140 feet shall be first raised straightaway to a depth of 50 feet where he waits 10 minutes, then to 40 feet for 10 minutes, 30 feet for 20 minutes, 20 feet for 30 minutes, 10 feet for 35 minutes, and then he leaves the water abruptly.

The difficulty and danger is the tendency on the part of the workers to curtail these weary waits, and get away from work as soon as possible. It is important that all fat subjects, and all those who have shown a susceptibility to compressed air sickness, and all those not in absolutely sound bodily health, shall be excluded from working in highly compressed air.

CURATIVE.—It was early discovered by the caisson workers themselves that the only remedy for the malady was to re-enter the high-air pressure.

A recompressing apparatus in the form of a medical air lock is now supplied at all caisson works, and on all ships engaged in deep salvage. On the appearance of any symptoms the worker is placed in the compressing room and the pressure is run up to the full pressure at which he has been working. When it is usual for the symptoms to ameliorate rapidly or disappear. After the recompression the decompression must be carried out very slowly, for the bubbles once formed in the tissues are not easy to get rid of, though they may be kept at a small size by the pressure. Cases apparently at the point of death with cyanosis and coma have many times been completely recovered in a few hours by recompression. When symptoms have appeared, the decompression should take at least 5 hours. Caisson workers and divers should sleep and live close to the medical air lock that they may be near aid during the first hours following decompression. The paralysis when once established is to be treated upon ordinary lines.

ANOXAEMIA

Definition.—A series of phenomena which result in the living animal from deficiency in oxygenation of the tissues in the absence of carbon dioxide retention.

Pathology.—The condition is directly referable to lack of oxygen and lowered internal respiration. Anoxæmia is divided into three classes, with widely differing causal mechanisms :

1. *Arterial anoxæmia.*—This is due to a deficiency in the oxygen content of the arterial blood, the oxygen-carrying power being normal and the carbon dioxide discharge unhindered. It is apt to appear whenever the oxygen content of the arterial blood falls below the normal limit of 94 per cent. of its total capacity, and it may or may not be associated with cyanosis. It is the usual result of breathing a rarefied atmosphere in which the partial pressure of oxygen is lowered, and in this connection is known as "mountain sickness" or "altitude sickness" when heights approaching 20,000 feet are reached. The characteristic phenomena can be produced at will by respiration within a partially exhausted chamber, and they can be obviated at high altitudes by adequate oxygen addition in respiration. Arterial anoxæmia is also present to some extent in those pulmonary diseases in which there is damage to the respiratory epithelium, obstruction to the air passages and when prolonged shallow breathing occurs, as in pulmonary œdema, emphysema and pneumonia, and in these conditions oxygen addition is valuable if its administration can be very prolonged.

2. *Stagnant or passive anoxæmia.*—This results when, on account of some fault in the circulatory mechanism, the passage of the blood through the tissues is too slow to provide for adequate oxygenation. It is the common happening in the circulatory failure of cardiac disease. There is here no fault with the oxygen content of the arterial blood. The oxygen saturation of the venous blood falls lower than 65 per cent. of the normal, and the normal difference between the oxygen saturation of the arterial and of the venous blood, which is 20 to 30 per cent., is exceeded, and there is always cyanosis, which appears when the reduced hæmoglobin content reaches 40 per cent. of the total hæmoglobin. Since the arterial blood oxygen content is not at fault, oxygen administration is useless to relieve this condition.

3. *Anoxic anoxæmia*.—This results from a deficiency in the oxygen-carrying power of the blood, either by reason of deficient hæmoglobin content, as in the anæmias, or by fixation of some of a normal hæmoglobin content, as methhæmoglobin, sulphæmoglobin, or carbon monoxide hæmoglobin. In the anoxic varieties, cyanosis does not occur, however severe the anoxæmia, for the reason that cyanosis only appears when 40 per cent. of a normal hæmoglobin content exists as reduced hæmoglobin. Therefore, an anæmic patient with 50 per cent. hæmoglobin would require 90 per cent. of the total hæmoglobin present to be reduced for the appearance of cyanosis. Oxygen administration is of no avail in anoxic anoxæmia.

ALTITUDE SICKNESS; MOUNTAIN SICKNESS.—There is considerable difference among individuals as regards liability to the appearance of symptoms at low atmospheric pressures, some suffering earlier and more than others. The immediate effect of exposure to such pressures is to cause rapid concentration of the blood and therefore a relative increase of the ratio of the hæmoglobin to the volume. A 10 per cent. rise in the hæmoglobin ratio may occur after 20 minutes' exposure. This is in part produced by the rôle of the spleen in acting as a reservoir for the erythrocytes, which are discharged rapidly into the general circulation under these circumstances. This serves as a compensation for the oxygen-want of the tissues, and its occurrence is associated with a disappearance or amelioration of the initial symptoms of oxygen-want. In those who remain at a bearable high altitude many weeks, some degree of acclimatisation occurs, and this is associated with hyperactivity of the blood-forming organs and a true erythræmia. The anoxæmia produces a hyperglycæmia, and there is at first an alkalæmia from increased ventilation, which subsequently lessens.

Symptoms.—*Mental effects* occur most importantly when rapid ascents to high altitudes are made in aviation, and consist of a gradually increasing dulling of perception, of which the subject is usually unaware. There is an increasing inaccuracy and lethargy of mental functions with a tendency to torpor and loss of memory. The skilled photographic observer takes eighteen photographs upon the same plate, the observer throws his valuable notes overboard, the pilot makes for a wrong destination or goes to sleep, and the fighting scout forgets to go into action. On return to land a muddled and confused memory of what has happened during the flight is all that remains. Lesser degrees of this condition have led to great errors in judgment, foolhardiness, apparent cowardice and irresponsibility in military aviation. So insensibly does this mental paralysis come on and so deep may be its effect before its presence is realised, that in Tissandier's balloon ascent in 1875, all three aeronauts, though provided with oxygen apparatus, were paralysed beyond movement before realising the necessity for using it, and two of them lost their lives. Diminution of auditory perception becomes so great at high altitudes that the aeroplane engine becomes almost inaudible.

Respiratory effects.—At an altitude of 12,000 feet, nose-breathing ceases, and above this height the breathing deepens into hyperpnœa, which may be most distressful and may be periodic. The dyspnœa is greatly increased on exertion and is accompanied by cyanosis. Even such acts as talking and using a pressure pump may greatly increase the dyspnœa.

Muscular weakness.—Accompanying the mental lethargy is an increasing condition of muscular weakness. The slightest exertion is hard work. The

machine is difficult to fly at very high altitudes, and the marksman shoots badly, and the mountaineer becomes incapable of taking exercise.

Other symptoms which may occur are—(1) headache, which may be very intense and which is very usually met with in prolonged exposure to high altitudes, as in mountain climbing; (2) spasmodic gulping accompanying the hyperpnœa; (3) fainting on exertion; (4) vomiting; and (5) hæmorrhage in the form of epistaxis, both of which are rare; and (6) frequency of micturition, which is common.

The mental effects are most conspicuous in aviators who had to make prolonged flights at very high altitudes during the War of 1914–1918 before the regular use of the oxygen apparatus. The dyspnœa, headache and muscular effects have been most troublesome in mountain ascents where exertion is unavoidable.

Death has occurred only in balloon ascents to gain a great altitude, and it occurs very rapidly, and is preceded by general muscular paralysis. Glaisher and Coxwell survived 29,000 feet by a lucky chance after complete paralysis of the limbs had set in. Sivel and Croce-Spinelli died at a height of 27,500 feet, while Tissandier, who was with them, survived. The after-effects of exposure to high altitudes have been well described by Birley, who, after observing many flight landings after high patrols during the War of 1914–1918; wrote: "The gait of the men on landing is unsteady and laboured. Reports are laboriously made out (there being a general disagreement as to what was seen and done). Tempers are short, every one looks and feels tired, and the idea uppermost in the mind is to lie down and go to sleep. Severe frontal headache is common; it may persist until the following day and at times proves incapacitating. Appetites are poor and spirits are depressed. It is easy to understand that a repetition of this kind of work over any length of time was rapidly productive of deterioration of mental and physical well-being."

Remarkable individual tolerance to anoxæmia occurs in some subjects, but this tolerance tends to disappear with repeated long exposure. Physical fitness and training increase toleration up to a certain point, whereas unfitness and especially digestive disturbances lower tolerance, and the latter are apt to induce vomiting.

Treatment.—Since the symptoms are due solely to lack of oxygen they can be entirely avoided by the use of a portable apparatus to deliver the necessary oxygen by all those who have to encounter an altitude of over 15,000 feet. Professor Dreyer's apparatus is portable, compact and satisfactory, and its essential feature is the regulation of oxygen delivery by an aneroid controlled valve, so that the amount of oxygen delivered varies in inverse proportion to the barometric pressure of the atmosphere surrounding the instrument and consequently in direct proportion to the altitude.

When symptoms have developed, the immediate treatment requisite is the cessation of exertion, the provision of oxygen if available and a speedy return to a lower altitude.

The late JAMES COLLIER.

SEA-SICKNESS AND ALLIED CONDITIONS

Definition.—Sea-sickness is a disorder of gastric and intestinal function brought on in susceptible subjects by travelling on the sea, and a similar disorder occurs in many persons under various other conditions in which they are subjected to repetitive irregular motion in different, and especially in unaccustomed, planes.

Ætiology and Pathology.—It is well known that irregular and unaccustomed stimulation of the labyrinths causes nausea and vomiting, and also other disorders of function in the structures innervated by the vagus or parasympathetic system; and in sea-sickness and allied conditions, excessive stimulation of the labyrinths is by far the most important causal factor. Another influence is the reception of irrelative impressions from the other afferent organs which subserve the orientation of the body in space and the appreciation of movement, viz., the eyes, and the postural sensory system of muscles and joints; while psychological factors, especially apprehension, also play a part. Excitement and fear help to prevent sea-sickness. Stimulation of the labyrinths occurs under all conditions in which the body is subject to a succession of accelerations and decelerations, as in a ship at sea, in an aeroplane, in a swing, and, to a less degree, in a railway train or motor car, and even during dancing, and susceptible subjects are liable to sickness under all such conditions.

The degree of susceptibility varies greatly in different individuals. Early infancy is immune from the affection, since the orienting mechanism has not attained full physiological activity, and old age is relatively immune, probably from lessening irritability of the nervous system. Individual hypersusceptibility and individual immunity are very common, and the readiness with which tolerance is acquired by training varies greatly in different people. Personal immunity is, for the most, relative only, for there are few who can pass through excessive and prolonged stimulation without developing some of the characteristic symptoms. The development of tolerance by habitude varies greatly. Some develop tolerance readily, and others with great difficulty. Years of continuous sea-going may pass before any tolerance is developed, and Admiral Nelson never acquired any.

Of the many adjuvant factors the more important are apprehension, or the full expectation of being sick, the smell of the ship, heat, a stuffy cabin, and the presence of others suffering from sea-sickness.

Symptoms.—The initial symptoms are a loss of the usual feeling of well-being, accompanied by a feeling of abdominal or visceral discomfort. Salivation, gaping and yawning follow, with irregularity of respiration, flatulency, pallor of the face, and a sense of squeamishness as though at any moment vomiting might occur. Many subjects at this stage have a desire to defæcate. These early symptoms are followed by severe nausea, retching and vomiting. In many cases the vomiting is of brief duration, but in others the gastric symptoms may become most violent and distressing, the vomit ultimately consisting of thin bile-stained fluid; there is complete anorexia, and in severe cases nothing can be retained in the stomach. In nearly all cases of any severity the visceral symptoms are accompanied by headache, giddiness, continued pallor, apathy, lassitude, weakness, dehydration and

prostration. These general constitutional effects may be very serious, and may lead to a condition of collapse. The eyes are dull, the facies becomes shrunk, perhaps greenish in hue, and inexpressive or dejected. The skin is cold and usually clammy, the tongue is coated, and both the breath and urine may contain acetone bodies. Pulse and respiration are quickened, and the blood pressure lowered. Little urine is passed, and constipation, after an initial bowel action, is usual.

Diagnosis.—This is seldom in doubt, but the possibility of other abdominal disorders occurring at sea must not, of course, be overlooked.

Course and Prognosis.—The symptoms usually subside rapidly when the voyage or other movement causing the condition is over, but sometimes dizziness, headache and gastric symptoms persist for a long time, and the patient is "good-for-nothing" until he has had a night's sleep. In persons taking long sea voyages, the symptoms usually lessen in a few days, reaction sets in, accompanied by a return of appetite, and convalescence is complete within a week, but symptoms are liable to return with an onset of rough seas. Some persons, on the other hand, never lose the symptoms until the voyage, however long, is over, and these may be reduced to a piteous condition of bodily weakness, from which subsequent convalescence is slow. Death appears rarely, if ever, to have occurred even in the most severe condition of bodily depression and starvation from sea-sickness alone. Apart from the long convalescence which may be required in severe and long-lasting cases, there seem to be no harmful results.

Treatment.—**PROPRYLACTIC.**—A susceptible subject should endeavour to secure an airy cabin amidships. The patient should take phenobarbitone gr. $\frac{1}{2}$ or hyoscine gr. $\frac{1}{100}$ two or three times daily for a day or two before going on board, and hyoscine gr. $\frac{1}{100}$ or vasano (which contains hyoscine) two tablets an hour before the ship sails. McArdle and Trotter, testing numbers of soldiers, found that drugs of the belladonna group were more efficacious than barbiturates, bromides, or chlorotone, and that hyoscine was much the best of the group. Most sufferers prefer to be supine, with the head low, but some find a closed cabin insufferable, and many are better in the open air, so that each should consult his individual preference. Confidence in the remedies advised is important, and an expectation of being sick is disastrous. Some subjects believe in a firm abdominal belt, and this is at least comforting and provides a feeling of confidence which may bring success. In troops about to land on a hostile shore fear or excitement is an important influence in preventing sea-sickness.

During the attack, it is important to keep the subject as still as possible; to calm the irritation of the nervous system with hyoscine preparations or barbiturates; to secure sleep; to prevent dehydration and acidosis; and on prolonged voyages to see that the patient is fed.

McArdle and Trotter found that after an initial dose of hyoscine gr. $\frac{1}{20}$, the drug could be repeated in doses of gr. $\frac{1}{100}$ at intervals of 6 hours for 48 hours without the appearance of any obvious undesirable side-effects, apart from some dryness of the mouth. Sips of fluid should be given, and sips of champagne are a popular remedy. Alkalies and sugar may be taken in fluid to combat ketosis. Food when given should be dry and in small quantities.

J. PURDON MARTIN.

ELECTRICAL INJURIES

Electrical injuries may be received from lightning-stroke, from accidental contact with high-tension conductors or faulty household electrical appliances, or from judicial electrocution where this obtains.

The severity of the injuries sustained in any given case depends upon other factors than the voltage of the discharge received, and thus it is that fatal injuries may be received from currents of comparatively low voltage (120 volts), and survival may follow the reception of currents of higher potential. It is said that a current of 500 volts is commonly fatal, and that alternating currents are more dangerous than direct. Voltages of over 1000 are spoken of as "high tension." The quantity of the current is also of importance. A current of 100 amperes is dangerous, one of 500 is likely to be fatal. In judicial electrocution the victim is subjected to repeated discharges (4 to 8), each lasting some seconds (5 to 50), of alternately high and low potential (500 volts alternating with 2000).

Pathology.—In those who survive electrical injuries complete recovery is usual—though not invariable—and it is clear that the lesions found in the nervous system in fatal electrical injury can hardly obtain even in slight degree in non-fatal cases. We shall first describe the lesions found in fatal cases.

In death from lightning-stroke the head is invariably struck, and there is a localised effusion beneath the scalp, which may be differentiated from the effects of a blow by the absence of abrasion. The body surface shows burns of various forms—linear burns, arborescent burns, and severe localised burns beneath any metal object which may have been carried in a pocket or worn on the person.

In the nervous system there are abnormal rents and fissures in the brain, the cerebro-spinal spaces are distended, the perivascular spaces enlarged, and the arteries at the base of the brain may show rupture of their muscular coats. In various situations the nerve cells show severe disruptive changes. In the past it has been assumed that these lesions are due to the passage of an electrical current through and over the body, but in a recent analysis of the circumstances of electrical injuries from the point of view of physical science Blake Pritchard has shown that this passage is inadequate to account for the nervous lesions, and that two factors are operative. These are the passage of current, and the charging of the body with electricity. It is the latter factor which alone is capable of producing the lesions found in the nervous system. The following brief summary is taken from Pritchard's account (*Lancet*, 1934, I. 1163).

If a man make contact with a conductor at high potential, or if he be struck by lightning, he will suddenly become highly charged with electricity. A current will pass through him only if he is in a position to lose this charge. If he is not insulated from earth the charge will pass rapidly through and over him, and will not accumulate upon him. This rapid passage will give rise to heating, electrolytic and mechanical effects, but these alone do not produce the lesions observed in fatal cases.

If he be more or less effectively insulated from earth, his body surface will become highly charged, and electrostatic forces will develop from the

mechanical repulsion which is exerted between similarly charged particles or bodies. A charged body will be repelled from all similarly charged bodies, and all the constituent elements of the body which carry the charge will be repelled from one another. Thus it is that when more than one object is struck by lightning, they are flung apart; a man is flung several yards from a tree under which he has been standing; or two men simultaneously struck are flung away from each other; a parcel held by an individual struck is hurled out of his grasp, and also his clothes, belt and boots are burst and torn off him in fragments, and he may be stripped naked. Within his body the same disruptive forces are at work, and produce lesions in proportion to the rigidity and cohesion of the tissues. The charge upon his body surface will make each particle of the surface repel each other particle, the whole surface will tend to expand away from the body, and this sudden expansile force will pass inwards as a wave of decompression. In this way we may account for the characteristic disruptive lesions found in the brain.

It is probable, then, that the electrostatic effects play a determining part in the production of the nervous lesions, and that these in their turn are largely responsible for a fatal issue when this ensues.

The actual passage of the current has heating and electrolytic effects, and Pritchard has tried to assess the importance of these. In legal electrocution, where alternating currents are applied in the manner and of the strengths described earlier, it is possible to form a fairly precise estimate of the heating effects. The current probably passes chiefly in the body by the blood and cerebro-spinal fluid, as well, of course, as over the body surface, where it produces the characteristic burns. It is possible that currents of the orders used may cause a rise of temperature in the tissues they traverse of as much as 60° C. In lightning-stroke, the rise is probably much less. The higher rise named is capable of severely damaging the nervous system, but not of producing the lesions seen in fatal cases. The electrolytic effects are probably negligible as far as the morbid anatomy is concerned.

Symptoms.—Graphic accounts of the effects of lightning-stroke are given by H. A. Spence in his monograph, and are based upon an extensive experience in South Africa. When struck by lightning the individual may later have no recollection of the incident, or may speak of receiving a tremendous blow on the head. Others have complained of intense visual or auditory sensations, of pain in the trunk and limbs, of giddiness and other symptoms. The subject is usually unconscious, pale and pulseless, and respiratory movements are suspended. This initial state of suspended animation or apparent death is common after lightning-stroke, but apparently not so frequent after accidental electrical injuries from contact with conductors. It may be necessary to carry out artificial respiration for as long as an hour before—in non-fatal cases—respiration becomes normally established. There may be powerful and generalised muscular spasm for a brief period and the limbs may be in flexion, and it is because of similar spasm in the heart and muscular coats of the arteries that the victim is pulseless and pale. Surface burns of varying severity are seen, and examination of the scalp will reveal a localised swelling at or near the vertex, with no cutaneous abrasion.

As respiration becomes re-established—either spontaneously or after artificial respiration—the subject may become restless and resistive, crying

with the pain of muscular spasm. Later, he becomes drowsy, has headache, and for one or more days may not be fully alert.

The common voltages in Great Britain are under 250. If an individual merely touches a conducting element or a part of an appliance which is not insulated, he receives a shock which causes a violent and unpleasant tingling sensation in the limb concerned or throughout his body, and this is quickly cut short by withdrawal of the part of his body from contact with the "live" object. The subject may feel faint but has no external injury. The serious cases are those in which the individual grasps a metal lamp-standard or other object which has become electrified as a result of defect in the wiring. The flexor muscles of the grasping hand are at once thrown into strong spasm by the electrical stimulation, with the result that the patient cannot let go. The spasm quickly extends up the affected arm. Almost instinctively he brings up his other hand and tries with it to release his first hand, and if he again catches the object by an electrified part, the muscles of both arms are quickly tetanised, and the spasm spreads to his chest and other parts of his trunk. The patient becomes speechless and pale, then cyanosed and convulsed, and loses consciousness. Unless the current can be switched off quickly death may result, but the degree of electrocution varies considerably according to the degree to which the patient is insulated. If the current is switched off within a few minutes the patient usually recovers consciousness quickly, but suffers from a variable degree of general shock and muscular spasm. Artificial respiration may be required. In another group of cases persons are electrocuted in their baths. Since water is a good conductor of electricity the insulation of an electrical appliance may be impaired if it is splashed with water or by the deposit of moisture upon it. An individual standing or sitting in a bath may pick up an electric hair-dryer or touch an electric heater, probably with a dripping hand. Instantly electricity passes over the patient's wet body, and the water and the metal of the bath become charged with it. The symptoms which ensue in the occupant are those already described, and unless the contact is broken, death may follow rapidly.

Diagnosis.—Spence records instances in which the finding of a dead body has made it necessary to determine the cause of death. When this is due to lightning-stroke, the following signs are found. There is an effusion beneath the scalp without superficial abrasion, and streaks of "brushburn" will be found upon the body surface. The body will be more or less stripped of clothes. If a hat was worn, a hole will probably be found in it over the seat of the scalp lesion. Leather garments, boots and belts are burst. Of course, if the victim was hurled or flung down some other signs of injury caused in this way may be found.

Treatment.—When the victim is unconscious, white and pulseless, artificial respiration must be undertaken at once, and persevered with for at least an hour before abandoning the patient. Even when respiration is first resumed, it may fail again and artificial respiration must be kept up until normal breathing movements are fully established. When consciousness is regained, the patient may complain of severe headache and of painful muscular cramp. The latter should be treated by massage. The usual restorative measures employed in severe shock may also be used, but the essence of treatment in severely shocked and unconscious patients is the carrying out of artificial respiration.

372 DISEASES DUE TO PHYSICAL & CHEMICAL AGENTS

The superficial linear burns of lightning-stroke may smart if exposed to the air, and are best covered by ointment, but they usually heal without searing. The deeper burns related to metallic objects carried by the victim, or to the points of entry and departure of the current in accidental injuries from contact with conductors, will sometimes require the ordinary treatment of burns according to their depth and extent.

The very rare residual neurological symptoms and disabilities may have to be dealt with according to their character and severity.

F. M. R. WALSH.

Revised by J. PURDON MARTIN.

THE EFFECTS OF HEAT

Under this heading are included those important conditions which result from exposure to high temperature. They are (1) heat exhaustion; (2) heat cramps; and (3) heat hyperpyrexia (heat-stroke, sun-stroke, heat retention).

Ætiology.—The factors which lead to these affections are divided into the environmental, and the individual.

Exposure to heat is the environmental necessity. Naturally, cases are most common in the tropics where there is danger in any shade temperature above 110° F., though heat exhaustion is not rare on a hot English summer day. There is, however, no special quality of solar rays to blame, for in experimental work direct exposure of the head to the sun is well tolerated if other factors are favourable, while heat stroke is common in the gloom of a ship's stoke-hold. Those who live well exposed to the sun at high altitudes do not suffer like those on the plains. In tropical campaigns the rise in case incidence appears to lag behind the rise of atmospheric temperature by a few days. In individual instances illness follows exposure by some hours, suggesting some cumulative effect.

Furnacemen, foundrymen, forge hammer workers, ships' firemen, iron and glass workers, and miners in deep mines run the risk of undue exposure to heat, and it is in these men that heat cramps are to be expected. In tropical countries, laden troops on the march readily succumb to heat-stroke.

Climate, atmosphere, and in particular humidity must be considered. A heat wave in any country leaves its quota of cases: in deserts without shade, and countries where day and night temperatures are both high, there is more danger. Most important of all, an atmosphere with a high humidity hinders heat loss from the body, and in motionless air where the wet-bulb thermometer reads 83° F. there is considerable chance of heat-stroke: still and poorly ventilated atmospheres themselves predispose to it, and the value of fans is self-evident.

Dwellings must be made of thick non-conducting material if they are to be protective, and in this respect a tent is of little use. Buildings should be well ventilated, and it has become almost instinctive for people in tropical climates to open their windows only in the cooler parts of the day.

Clothing needs to be light and loose-fitting; experienced workers in hot damp places have found that they are most comfortable if they wear a cotton shirt than if they are stripped to the waist and bathed in sweat.

Deficiency of salts in the body is just as important as any of the above

factors and is thought to be the basis of all conditions attributable to heat. Sweat contains about 0.25 per cent. of sodium chloride, and by sweating a man may lose as much as 30 g. of salt in a day. In the absence of added salt, such a depletion may predispose to heat-stroke, and is certainly the principal cause of heat cramps. This fact was discovered by J. S. Haldane in the deep South Staffordshire coal-mines. He was the first to suggest that the cramps would follow the drinking of water, but that they could be avoided if salt were added to the water. Directly linked with sweating is the amount of exertion undergone, so that heavy work in a hot and unfavourable atmosphere is particularly dangerous.

Predisposing factors include malaria, fatigue, alcoholism, metabolic diseases, gastro-intestinal disorders in which water and salts are readily lost, and the previous use of strong purgatives, thyroid, or atropine. Native races are usually immune unless there is other disease present; old people are susceptible, so are those who have previously been affected. Some people have a constitutional inability to perspire. What is especially noteworthy is that an unacclimatised man is more susceptible than a veteran, for, during acclimatisation, there is physiological conservation of salt and the salt content of the sweat falls to 0.09 per cent.

Pathology.—In heat exhaustion a direct heat action upon the brain probably occurs in addition to the salt loss, and the picture is akin to that of surgical shock. In heat cramps there is loss of salt and the serum chloride is lowered. It may be that the corresponding ionic changes at the myoneural junctions initiate the cramps, particularly as the muscles most in use are affected.

In heat hyperpyrexia there is derangement of the heat regulating centre, but salt depletion is also important, for the urinary chloride figure is very low. There is some evidence of increased metabolism in addition to indicanuria. That experimental hyperpyrexia can be induced with *beta*-tetrahydro-naphthylamine has been used as evidence to support a theory of auto-intoxication by katabolites as the basis of heat-stroke.

After heat hyperpyrexia rigor mortis occurs early and so do putrefactive changes. Edema and hyperæmia of the brain and lepto-meninges occur, and the nerve cells in the grey matter show degenerative changes. In severe cases petechiæ occur in the skin and mucous membranes, and venous congestion is present in all organs.

1. HEAT EXHAUSTION

Acute symptoms may overtake a man at his work. There is an attack that suggests syncope, he becomes weak and faint, pale and prostrated, giddy and sweating. The pulse is weak and rapid, the blood pressure very low, and the signs resemble those of shock. He may become unconscious. The temperature is normal or subnormal, respirations shallow and sighing, and the pupils dilate. Recovery may be quite rapid, but there is danger of hyperpyrexia later if the patient is not carefully treated for some days.

Treatment.—Lay the patient on his back in a cool place, loosen the clothing, and apply massage or local heat to the limbs. A warm bath may do good: give saline drinks, perhaps intravenous salines, and keep him under observation.

2. HEAT CRAMPS

In the second half of his shift at work a man may be seized with violent cramps. He is often of poor physique. The symptoms are more likely to occur should he have been drinking water in quantity after a bout of sweating. The cramps are agonising, starting usually in the calves, moving later to the arms and abdomen, and he may appear knotted up in an attitude of flexion with contorted muscles. There may be intestinal colic and vomiting, for visceral muscle is not immune. In severe attacks it may take half a dozen men to hold down the sufferer, and afterwards he may say he would rather die than endure another attack.

Treatment.—Prophylaxis is important. Those who work in conditions predisposing to heat cramps may have taken to shellfish, bacon, kippers, milk, and even salted beer. Extra salt is needed, and this is provided by effervescent tablets containing 5 grains of sodium chloride flavoured with lemon. The men will relish a daily salt intake which would be nauseating to others. The usual requirement above a normal day's intake is about 15 g. and double this amount in the uninitiated. For the attack, morphine may be necessary and sometimes intravenous saline.

3. HEAT HYPERPYREXIA

This is the most serious effect of heat. It may occur suddenly and proceed to coma and convulsions, but more commonly it begins gradually with irritable, querulous behaviour, malaise and headache, and the warning symptoms of polyuria, dryness of the skin, drowsiness, intolerance of light, tingling and cramps in the limbs, and a temperature of 100° to 102° F. This may last up to 48 hours; if by then the patient is not treated, there is a sudden rise of temperature to 110° F. or more, the pulse becomes rapid and irregular, and there is mental excitement and delirium progressing to coma and convulsions. Now the face is flushed, the conjunctivæ congested, the pupils dilated, becoming constricted later, and the breathing stertorous. There may be albumin and indican in the urine, and in some cases ketone bodies. When coma is reached death follows quickly, sometimes with acute heart failure and œdema of the lungs. After recovery, residual dysarthria, ocular and other neurological signs may be seen, the temperature may stay at 102° to 103° F. for days, and even when it has subsided the patient may be left for a long time susceptible to a recurrence of hyperpyrexia, he may suffer headaches and be unable to sweat. Variations of the clinical picture have been described in which the symptoms are predominantly gastric for 4 to 10 days when hyperpyrexia suddenly follows, or in which the main features are diarrhœa and vomiting.

Differential Diagnosis.—Heat hyperpyrexia may resemble the cerebral form of malaria, or may follow directly upon any other serious physical illness. In malarial districts the coexistence of this disease should be presumed even if the blood films are negative. In pontine hæmorrhage there is also hyperpyrexia, but it is a late sign. A quantitative estimation of urinary chlorides is valuable evidence of heat hyperpyrexia if it gives a value below 3 g. in a 24 hours' specimen.

Treatment.—**PROPHYLACTIC.**—In unfavourable climatic conditions special care must be taken and physical exertion restricted to the morning and evening. Men must have washing facilities, adequate sleep, plenty of salt in their diet, and ample water to drink, but they should not take alcohol in the heat of the day. Extra sodium chloride should be given in doses of 10 grains to a pint of drinking water. In exceptionally hot weather hospitals should have wet screens and fans, anæsthetics and operations should be as few as possible, and care exercised in the use of such drugs as atropine.

CURATIVE.—When any possibility of malaria exists full doses of quinine are needed at once. The temperature should be reduced and every step taken to increase heat loss by evaporation, as this is more effective than cooling by application of ice. The patient is placed on a bedstead on a porous mattress with free circulation of air all round and below him. If these facilities are not to hand, or if the humidity is very high, he may be put into a bath of cold or iced water up to the neck and massaged vigorously. When the temperature is being rapidly reduced by any means rectal temperature readings every minute are necessary, and the process must be stopped at 103° F. Then the patient is wrapped up and ice packs applied to his head and neck. Rectal injections of iced water are only of limited value. Rubbing with ice merely causes vasoconstriction, and delays the cure.

The salt depletion is made up by drinks or rectal administration of normal saline, or, except when there is heart failure or convulsions, by intravenous saline. Extra salt is needed for some days. Heart failure itself is combated by a venesection of 10 to 20 ounces. Any stimulant which might induce convulsions is contra-indicated. Since the convulsions are due to cerebral œdema venesection is of value. Withdrawal of cerebro-spinal fluid by lumbar puncture is more effective than the use of hypertonic rectal solutions: sometimes an anæsthetic is needed.

The immediate danger past, the patient must be watched carefully in a quiet room for three weeks. Bromides or barbiturates may be needed. He should then be sent to a healthier atmosphere and must avoid any possibility of another attack for months afterwards.

INJURIES FROM X-RAYS

Ætiology.—Within 3 months of the announcement by Röntgen of his discovery of X-rays in November, 1895, it became known that conjunctivitis could occur after some hours of exposure to irradiation. A year later erythema, swelling, and necrosis of the skin, alopecia, and chronic radio-dermatitis were reported. In 1897 attention was directed to the acute constitutional symptoms. In 1902 a case of cancer was recorded following chronic ulceration caused by X-rays. The first death recognised as due to the action of X-rays occurred in 1914. In 1922 it was estimated that 100 radiologists had died from malignant disease due to their occupation. Deaths occurred among radiologists exposed to X-rays before the importance of adequate protection was realised, and unfortunately still occur.

So far nearly all the victims have been research workers, radiologists, laboratory assistants, technicians and nurses. Cases of industrial origin

376 DISEASES DUE TO PHYSICAL & CHEMICAL AGENTS

did not occur until later, because the use of X-rays in industry began later. Industrial workers, unlike professional workers, are often quite ignorant of the possible dangers of the apparatus used, so that industry is now, in respect to the use of radio-active substances, about where medical practice was in 1914. There is, however, no reason why the lamentable history of the pioneers in the medical field should be repeated. The human experiments have been made, the tragic results of carelessness demonstrated, and the measures necessary for adequate protection are known and available to anyone who cares to learn them.

X-rays may be used in industry for the detection of defects, cracks and blow-holes in castings, of defects in alloys from faulty mixture, of erosion in cables or gas cylinders, and of defects in reinforced concrete or in weldings. X-rays are also used to sort fresh eggs from stale, to reveal mineral adulterants in vegetable foods, and weevils in grain. For the examination of metals and all thick objects very penetrating rays must be used.

Symptoms.—Injuries which follow a short single exposure, or perhaps several exposures, may vary enormously in intensity. In mild cases there is simply a transient reddening, lasting a few days and followed by scaling and loss of hair. If the burn is deeper, blisters appear which may be serous or purulent, and the condition resembles that following a scald but is less acute and slower to heal. Sometimes the process, instead of disappearing in a few weeks, penetrates to the deeper layers of the skin and to the subcutaneous tissues, with the formation of a leathery slough, surrounded by a brawny indurated swelling with ill-defined limits. The process is exceedingly slow and obstinate, and has a tendency to progress and to resist treatment in a remarkable way. It is at times very painful.

In chronic X-ray dermatitis the changes in the hands begin round the base of the nails as a peculiar erythema and gradually increase. Transverse and longitudinal ridges appear on the nails, which become brittle, assume a characteristic dirty brown appearance, tend to separate from the matrix, and eventually thicken and form shapeless masses. The skin becomes uniformly red and atrophied; small warts appear, increase in size and number, and, when situated over the knuckles, crack and cause much pain. Later the dry thickened skin shows telangiectases, absence of hair, paronychia and ulcers which are slow to heal and prone to break down. The hair follicles and the sebaceous and sweat glands completely disappear in cases of long standing. The freedom of the palms of the hands may be due to the naturally thicker skin there, but the greater liability to exposure of the backs of the hands and fingers is probably the more important factor. The lesions are as a rule slowly progressive. Post-irradiation telangiectases, which have been regarded as compensatory for obliteration of the vessels in the corium, usually appear within 2 years, and sometimes in the absence of an initial erythema; in some instances the interval between irradiation and the appearance of telangiectases is prolonged, even to 15 years. If exposure is continued the lesions may progress to involve the tendon sheaths and joints. There may be intense pain, of which the severity is out of proportion to the size of the lesions; it is caused by the exposure of nerve-endings.

Squamous-celled carcinoma is almost always the form of malignant disease which has followed excessive X-ray exposure and long-continued

X-ray dermatitis in man. Although most often seen in radiologists and manufacturers of X-ray apparatus, X-ray carcinoma may also occur in patients who have undergone treatment by X-irradiation. The interval between the onset of chronic X-ray dermatitis and the appearance of malignant disease varies from 3 to 27 years. The average of 35 cases was 7 years. The age incidence from 35 to 50 is comparatively early, that of ordinary carcinoma of the skin being between 55 and 58. The most frequent site of the growth, which is not uncommonly multiple, is on the backs of the hands and fingers, and the hand more exposed appears to be the one more severely affected, the left in radiologists and the right in those engaged in the manufacture of apparatus. Among radiologists carcinoma usually develops in an ulcer, less often in keratotic areas. The predominating symptom is pain, which may be constant and very severe, and has been ascribed to invasion of the terminations of nerves by the growth and to neuritis. Occasionally basal-celled carcinoma results from X-irradiation. In one case a basal-celled carcinoma of the scalp appeared 18 years after epilation for ringworm. A case has also been recorded of multiple basal-celled carcinomas on the trunk of a radiographer.

Constitutional symptoms only became prominent after the introduction of deep X-ray therapy, in which massive doses of deep penetrating rays were given. Severe constitutional symptoms may occur. They are nausea, uncontrollable vomiting, sometimes with hæmatemesis, diarrhoea, with the passage of blood, abdominal pain and distension, fever up to 104° F., restlessness, profound prostration, progressive cardiac failure, small rapid pulse and dyspnoea. When death has occurred it has usually taken place about the fourth day from the onset. Both animal experiments and necropsies of human victims show that the application of X-rays to the abdomen may result in necrosis of the intestinal mucosa. As long ago as 1905 unsuspected sterility was found in 18 persons who had for various periods been exposed to X-rays. The acute degenerative changes in the testes are followed by fibrous atrophy. Anæmia occurs in X-ray workers. After small doses of X-rays, the lymphocytes are first increased in number, then diminished. The red cells may also be increased at first, but anæmia sets in later and may become extreme. In patients who recover, the anæmia is slower to disappear than is the leucopenia. True aplastic anæmia does not occur.

Diagnosis.—The possibility of exposure to radium should always be excluded before attributing what appears to be aplastic anæmia in an X-ray worker to X-irradiation.

Treatment.—**PROPHYLACTIC.**—Within the first few months after their discovery it was found that X-rays were stopped more effectively by lead than by any other common metal. Hence lead for protection came into use very early. To-day lead, lead glass, lead rubber and lead bakelite are extensively used. Transparent lead glass windows in tube containers were first employed about 1900. At that time the need for protecting both operator and patient during radiographic exposure was very great, because low voltages were used, with consequent long exposure to a very soft and easily absorbed radiation. For example, to radiograph the spine required exposures up to 1 hour. That the radiologist was not more frequently affected by the scattered radiation of such exposures was due to the fact that during them he might retire to another room to see other patients.

378 DISEASES DUE TO PHYSICAL & CHEMICAL AGENTS

About 1903 there appeared a multitude of protective devices to be worn by the radiologist, including apron, jacket, gloves and goggles. This type of protection gradually reached its peak about 1914, when necessity threw caution to the winds, and the more elaborate devices gave place to means of protection which were built into the apparatus.

To-day there is international agreement as to the most effective methods of prevention. In Great Britain such methods have been widely adopted, and although they have no strictly legal recognition, powers of inspection and approval have been placed in the hands of the National Physical Laboratory. It is important that the industrial physician should plan measures for the protection of employees against the dangers of X-irradiation, for in large manufacturing establishments there are X-ray departments for diagnosis as extensive and as much used as the average hospital department. Here the problem may include protection of workers in neighbouring rooms, for unless walls and floors are very thick or are rendered impermeable by the use of lead, X-rays may pass through them and cause injury.

SYMPTOMATIC.—X-ray carcinoma should be treated either by diathermic coagulation under local anæsthesia, or by radium. Slight degrees of anæmia recover on removal from exposure. In more severe degrees iron must be used, and when this fails blood transfusion is necessary.

INJURIES FROM RADIO-ACTIVE SUBSTANCES

Ætiology.—The gamma rays of radium appear to have a greater tendency than X-rays to cause aplastic anæmia; this impression is supported by the experimental evidence that the penetrative gamma rays of radium reach the bone marrow more readily than do X-rays. Three fatal cases of aplastic anæmia were reported in the London Radium Institute in 1920, one in a nurse and two in laboratory assistants. In 1925 the death of a chemical engineer working with radium and thorium-X was recorded.

The chief use of radium salts in industry has been in the manufacture of luminous paint for the figures of clocks and watches, and certain important parts of the machinery of aeroplanes. At two factories, one in New Jersey and the other in Connecticut, 38 deaths occurred among factory girls, chemists and physicists. The paint used contained insoluble radium sulphate, mesothorium and radiothorium. The girls affected introduced the paint into their mouths through the habit of pointing the brush between their lips and swallowed it for periods of from 1 to 4 or more years. The insoluble radio-active materials became deposited in the body to such an extent that even during life radio-active emanations could be detected in the expired air.

After death, bone was found to be the tissue in which the materials had mainly accumulated. The anæmia resulted from the continuous bombardment of the hæmatogenous marrow by alpha particles, and it was found that these changes were quite different from those due to external irradiation with beta and gamma rays only. Radio-activity in the bones and teeth was demonstrated by autophotography. The bones when placed directly on photographic plates produced impressions in as short a period as 3 days. The total amount of radio-active material necessary to produce

fatal results is extremely small. It is sufficient for 0.01 mg. to be distributed over the whole skeleton to produce a terrible death years after it has been ingested. Radium is thus the most deadly poison known; tetanus toxin previously held the record with a lethal dose of 0.22 mg.

Symptoms.—Dermatitis due to radium, isolated by the Curies in 1898, was reported in October 1900. Insufficiently protected tubes of radium salts kept in the waistcoat pocket for 6 hours produced reddening of the skin and within 10 days or so ulceration. Dermatitis has been reported in a number of persons engaged in making radium preparations, and less often in medical men. The ill-effects of ingestion of radio-active substances include severe anæmia, sometimes aplastic, necrosis of the jaw, spontaneous fractures and sarcoma of bone. The changes in the blood have been referred to as *anæmia radiotoxica*. The red cell count may drop below one million and the hæmoglobin below 20 per cent. Leucopenia, granulopenia and thrombopenia all occur. Purpura is followed by more serious bleeding, such as menorrhagia, hæmoptysis, hæmaturia and retinal hæmorrhages. Necrosis of the jaw occurs. It is similar to that produced by phosphorus, and is attributed to infection supervening upon changes in the bone. In certain cases necrosis of the jaw does not occur, but after a number of years generalised changes in the bones develop with deformity and sometimes spontaneous fracture, a condition known as *radiation osteitis*. Bone sarcoma occurs in 25 per cent. of the cases of occupational mesothorium and radium poisoning.

Treatment.—Though medical practice is now almost safe so far as X-irradiation is concerned, matters are very different in the case of radium. There is no doubt that many people are affected by handling radium, chiefly by the gamma rays. Their penetrative powers are so great that it is not practicable to secure complete protection. In the case of persons who carry radium about, the weight of lead they can bear to carry only partly protects them. Surgeons handling radium are also ill-protected. In the case of a man using 120 mg. of radium in the treatment of carcinoma of the cervix uteri, protection is very difficult as each time he has to handle the substance closely and carefully. It is obvious that ingestion or inhalation of radio-active materials in industry is highly dangerous, and that all occupations involving the handling of such substances should be strictly controlled and supervised. In the watch industry, outside New Jersey and Connecticut, the practice of pointing the brush with the lips is unknown, and no ill effects have been observed in other countries.

ALCOHOLISM

Alcoholism is dealt with in this section mainly from the point of view of the physical effects. The subject may be conveniently divided into (1) acute alcoholism; (2) alcoholic coma; (3) dipsomania; and (4) chronic alcoholism. The section of Psychological Medicine (pp. 1870–1874) should also be consulted.

1. ACUTE ALCOHOLISM

Synonyms.—Acute Alcoholic Poisoning; Drunkenness.

Definition.—A person is said to suffer from acute alcoholism when as

a result of alcohol he is unable to do with safety to himself or others that which he attempts.

Ætiology.—The effect of alcohol varies in different individuals, and depends not only on the amount taken but also on the physical state and mental stability of the patient.

Pathology.—Repeated sublethal doses cause no pathological changes in experimental animals. However, alcohol enhances the effects of other poisons and accelerates such degenerative processes as atheroma. Clinical observations on healthy human adults support these findings. It is a matter of common experience that post-alcoholic intestinal symptoms, malaise and headache, are more apt to occur when some other poison is taken at the same time. Examples are tobacco and the harsh acids of badly prepared wines. In alcoholic intoxication, the blood and urine alcohol reach a level between 0·1 and 0·3 per cent. The basal metabolism is raised, and there is great water loss from over-breathing, sweating, diuresis and sometimes vomiting. Alcohol depresses nervous activity. Reaction time is prolonged and perception dulled. The special senses become less acute, weakness of accommodation and of ocular synergia occur with blurred vision and diplopia. The normal social inhibitions become dulled so that the animal tendencies escape repression, with consequent non-social or even anti-social behaviour. Indeed this lessening of inhibition is the end aimed at in taking alcohol, and allows a certain freedom and exhilaration in over-repressed persons. This escape from inhibition should not be regarded as an increase in general efficiency. In unstable persons, pathological mental tendencies may become uncovered, with resulting epileptic attacks either in the form of fits, or as "epileptic equivalents" such as *mania a potu* or automatism (see p. 1871).

Symptoms.—The clinical picture of drunkenness is well known. After sleeping the patient awakens with headache and the usual symptoms of a mild gastro-intestinal upset. As has been inferred before, there is little after-effect in the healthy person who drinks sensibly. People who have drunk unwisely or have taken too much tobacco will feel ill all the next day. They show the clinical picture of a mild melancholia with gloomy thoughts, poor volition and excessive irritability. Strong sensory stimuli are poorly tolerated. Mental concentration is poor, and there is marked lessening of general efficiency.

Diagnosis.—It is often impossible for an exact diagnosis to be made until the patient has been kept under observation, and this precaution should be taken where there is any doubt. No exact percentage of alcohol in the blood and urine can be fixed as the precise limit between sobriety and drunkenness for medico-legal purposes.

Prognosis.—Recovery usually takes place within 24 hours and can be hastened by appropriate treatment.

Treatment.—If the drunken person is seen before going to sleep, he should be given an emetic of warm sodium bicarbonate solution (60 grains to a pint) and subsequently encouraged to take a drink of water. The aim of this treatment is to remove any of the poison that remains in the stomach, to soothe the mucosa and to combat the dehydration. If the patient needs treatment and refuses it, apomorphine gr. $\frac{1}{16}$ or gr. $\frac{1}{8}$ hypodermically will induce vomiting within a few seconds and leave the patient amenable to subsequent treatment. He should then be put in a warm bed and allowed

to sleep as long as possible. On waking a Seidlitz powder should be given and the patient encouraged to take plenty of fluid. This is usually acceptable in the form of tea. If tolerated, dextrose in some form should be given. When anorexia is marked, food should not be forced. If a great deal of alcohol has been taken, two grains of calomel can be given half an hour before the Seidlitz powder. If the patient has to get on with his work, 10 grains of calcium aspirin will improve his general feelings and combat the headache. Large doses of ordinary aspirin often irritate the stomach and should be avoided, as most of the symptoms of the next day are due to the gastro-intestinal upset. To give bitter alcoholic drinks as part of treatment is contrary to all medical principles and has no real therapeutic effect.

2. ALCOHOLIC COMA

Synonyms.—Acute Alcoholic Poisoning ; Wet Brain.

Ætiology.—Individual susceptibility varies so much and case histories are so falsified by prejudice and folklore that there are no reliable figures of what constitutes a dangerous dose. Alcohol is much more dangerous in states of debility, whether such debility be the result of disease, exhaustion or hunger. Naturally beverages of high alcoholic content are more poisonous than those of low.

Pathology.—At post-mortem alcohol is present in all the body fluids. There is mucous catarrh of the stomach and evidence of right heart failure. The nervous system shows a moderate excess of cerebrospinal fluid and the superficial parts of the cortex are œdematous.

Symptoms.—These come on quickly. The euphoric exhilarated period is short, the patient becomes sleepy and soon passes into coma with stertor. Vomiting or even convulsions may occur during the early drowsy period, but neither of these symptoms is constant. In the coma, the patient lies in any position in which he is put, and is commonly found lying on his back. He is pale, collapsed and sweats profusely. In the early and middle stages he can be roused sufficiently to make a few disjointed remarks, and this has some diagnostic value. In these stages the pupils are dilated, the pulse full, the temperature subnormal, and the respirations deep. In the later stage the coma becomes dangerously deep, the pupils contract, the pulse weakens and the respirations are shallow. At all stages the limbs are flaccid, with diminished reflexes. In the early stages the plantar reflex is flexor, while in the later stages it cannot be elicited. Examination of the blood and urine show an alcohol content of 0.3 to 0.6 per cent.

Diagnosis.—It is of paramount importance to exclude cerebral trauma before making a final diagnosis of alcoholic coma. Sometimes the history of trauma is deliberately withheld by the person who has called the doctor. When there is a history of unconsciousness followed by a lucid interval and subsequent coma, this is good presumptive evidence of ruptured middle meningeal artery. The absence of such a history does not exclude this accident, as often the patient has taken alcohol, which implements the original concussion and does not allow the intermediate return of consciousness. Alcohol can precipitate other comas, notably diabetic coma, uræmic coma and epileptic coma. The urine must be examined in all cases, and when there is any doubt a lumbar puncture should be done. A careful

382 DISEASES DUE TO PHYSICAL & CHEMICAL AGENTS

general examination will reveal evidence of such conditions as renal disease or arterial degeneration, and may show scars on the tongue or elsewhere suggestive of epilepsy. Cerebral hæmorrhage or thrombosis must not be forgotten. Reference should be made to p. 160† and elsewhere.

Prognosis.—With adequate treatment that is not too long delayed, this is good provided that the patient is otherwise healthy. The prognosis is unfavourable in those with cardiovascular disease, or when the acute attack occurs in the course of chronic alcoholism. Miosis is an unfavourable sign.

Treatment.—Treatment is necessary to combat shock and dehydration. Warm the patient, raise the limbs, and give fluids. The stomach should be washed out with one quart of a warm aqueous solution of sodium bicarbonate (60 grains to a pint), and a rectal drip of warm water should be started immediately. If there be evidence of heart failure with gross venous congestion, venesection should be done provided that the measures to combat shock and dehydration have been applied.

3. DIPSOMANIA

Definition.—An intermittent compulsion to get drunk.

Pathology.—This is a compulsion neurosis.

Symptoms.—The periodicity varies in different individuals and in the same individual under differing stresses. Commonly it is about once a month. An irresistible desire to take large quantities of alcohol seizes the patient. Usually he begins drinking after work one day, takes a large amount, comes home with a bottle of spirits, and after drinking this becomes stuporose and has to be put to bed. The bouts tend to become more frequent. Usually no alcohol is taken between the attacks.

Prognosis.—A good deal of amelioration can be expected in expert hands; otherwise the outlook is not good.

Treatment.—The patient must be referred to a competent psychiatrist.

4. CHRONIC ALCOHOLISM

Definition.—A patient is said to be a chronic alcoholic when he cannot carry on his ordinary life without alcohol.

Pathology.—This is primarily a mental disorder. The psycho-pathology is dealt with in the section on Psychological Medicine (pp. 1836–1840). Physically alcohol enhances degenerative tendencies, such as atheroma, and implements the toxicity of poisons; these effects are well seen in experimental animals. Gastro-intestinal catarrh occurs and results in deficient absorption of essential food elements. This is made worse because the patient prefers drinking to eating. In advanced cases achlorhydria is found. Bronchial catarrh and conjunctivitis are common, probably as a result of vitamin-A deficiency. Deficiency of vitamin B results in parenchymatous degeneration of nerves, and wasting of brain cells with chromatolysis. Ultimately the brain may be so wasted that the post-mortem appearance simulates that of G.P.I. Pachymeningitis hæmorrhagica is sometimes observed. The well-known susceptibility to pulmonary tuberculosis may be related to dietary deficiency.

In the cardiovascular system atheroma and related degenerations are accelerated. However, it is a commonplace of pathology how little cardiovascular change there may be in an alcoholic subject. Gout is made much worse by alcohol, and osteoarthritis is common in alcoholics. The majority of persons with cirrhosis of the liver are heavy drinkers. No doubt some factor in addition to the alcohol is necessary to produce this condition, for it may be absent even in the worst chronic alcoholic. Alcohol is dangerous in diabetes, for it interferes with treatment and increases the tendency to complications.

Symptoms.—Typically the chronic alcoholic is a plethoric person with a plum-coloured complexion. The colour is most marked on the cheeks and nose. Its blue component is due to dilated small veins. After exposure to cold, the colour may darken to a deep mauve. The lips tremble, and there is a fairly coarse tremor of the hands. This tremor may affect the handwriting. The patient is fidgety, often wiping his mouth with his hand, fiddling with his tie, pulling at his ear or playing with his watch chain. He is restless in his chair, and often has tics involving the whole trunk or the head. He is often swift but superficial with his replies, and though his manner is calculated to be disarming he is inclined to be irascible. He readily responds to the mood of the examiner. His eyes have an appearance that is variously described as glassy or watery. The conjunctivæ are red. His appetite is poor, and he has a preference for spicy and pungent foods. He rarely takes any breakfast, and does not feel himself until he has had a drink. On rising he clears his throat of much viscid mucus, which he usually refers to as "my catarrh." Often the hawking induces an attack of vomiting. Cases with much gastric catarrh vomit either on rising or at a fixed time afterwards. He is usually proud of the freedom of his bowels, but when careful inquiry is made it is found that he has diarrhoea. Night-rising once or twice is common. The majority of cases have attacks of paræsthesia in the limbs from time to time, and on examination the reflexes are found sluggish and the calves tender. In the presence of arterial degeneration a cerebral vascular accident may occur at any time, but more frequently the final illness is uræmia.

Neurological Complications.—Some degree of peripheral neuritis is common (see p. 1812). *Korsakoff's psychosis* may be present (see p. 1872). Sometimes in alcoholic neuritis the pupil is very sluggish to light. In such cases, if the neurological signs overshadow the mental, the condition is often referred to as *alcoholic pseudo-tabes*; if, on the other hand, the mental signs predominate over the physical, it may be called *alcoholic pseudo-paresis*. These terms are self-explanatory. *Acute hallucinosis* or the more serious *delirium tremens* are acute psychoses and are dealt with in the section of Psychological Medicine (see pp. 1871, 1872).

Prognosis.—(a) **GENERAL.**—As regards cure this is often bad. In many cases, however, suitable management leads to a good all round improvement. Intercurrent diseases, especially those of the respiratory system, are poorly tolerated. Pneumonia and tuberculosis have a much worse prognosis in these patients than in normal people. Anæsthetics are taken badly, and there is more likelihood of post-anæsthetic complications.

(b) **NEUROLOGICAL.**—This has been greatly altered for the better since the true nature of these complications has been understood, namely, that

384 DISEASES DUE TO PHYSICAL & CHEMICAL AGENTS

they are due to deficiency of vitamin B₁. Provided that no permanent damage has been done, cure can now be obtained of both the neuritis and the Korsakoff syndrome.

Treatment.—(a) OF THE CHRONIC ALCOHOLISM.—This is difficult, and usually disappointing in the hands of the general physician. The underlying causes are mental and these need the attention of experts. Should it be necessary to treat the patient in his own home without a psychiatrist the friends should be spoken to earnestly, and everyone in contact with the patient must be above suspicion because absolute withdrawal of alcohol is essential. Since the patient has been used to this nerve depressor, he may experience severe withdrawal symptoms and some simple sedative such as paraldehyde (min. 120) should be available. Where paraldehyde is not tolerated, soluble barbitone (medinal) (grs. viiss) is suitable. The patient's appetite will be poor, and may be encouraged by a simple stomaehic before meals. After meals he should be given a sedative alkaline mixture, such as bism. carb. gr. 15, sodii bicarb. grs. 15, tr. bellad. min. 10, tr. card. eo. min. 120, aq. menth. pip. ad min. 240. He should be handled sympathetically, and any outstanding domestic difficulties and worries resolved. Graduated doses of strychnine are employed in many cases. Such treatment acts by suggestion. Better results will be obtained in these patients if at the beginning they are put to bed for a few weeks, and if the gastro-intestinal illness is treated intelligently. For psychological effect, the patient may be put on a rigid diet with all the quantities carefully prescribed and supervised. The form of the diet will depend on the circumstances, but it should be bland, well balanced, and rich in vitamins.

(b) NEUROLOGICAL.—Rest the affected parts, including the mind, and give large doses of vitamin B₁ (aneurine hydrochloride, thiamine hydrochloride). For the first two weeks, 10 mg. should be given intramuscularly every alternate day, and thereafter, twice weekly. In addition, 30 grams of brewer's yeast should be given by mouth twice daily. After recovery the patient should continue to take vitamin B₁ indefinitely.

ACUTE MORPHINE POISONING

Under this head can be included poisoning due to opium, diamorphine (heroin), and dilaudid, for the picture in each case is similar. (For chronic morphinism see p. 1874.)

Ætiology.—Poisoning occurs by accident or suicide, after ingestion or injection, though cases have followed rectal administration or absorption through wounds. The fatal dose is variable; of morphine, probably 2 to 3 gr. is needed, and of opium 10 to 30 gr., though less in some cases. Tolerance is easily established, but conversely children are unusually susceptible. The fatal period is from 6 to 12 hours, regardless of the dose.

Pathology.—Death is from respiratory failure, and necropsy reveals cyanosis of the head and extremities and dark blood. There may be a smell of opium in the stomach, and demonstrable quantities of the drug in the urine and organs.

Symptoms.—In 10 to 30 minutes if the drug was taken by mouth, or less if by injection, a transient phase of euphoria and exhilaration may be seen, then nausea and vomiting, later dizziness, heaviness in the head and

sleepiness, soon resulting in coma. The patient in coma shows slow stertorous respiration at 2 to 4 per minute, with cyanosis of the face, slow pulse, general flaccidity and loss of reflexes, perhaps an extensor plantar response, and pinpoint pupils. Sweating is considerable and the skin is warm in spite of a low temperature. Oliguria, pruritus and skin rashes are sometimes seen. The pupils dilate in the ultimate stage of respiratory failure.

Diagnosis.—Coma, stertor and constricted pupils are a suspicious triad. Pontine hæmorrhage finally shows a rising temperature.

Treatment.—Warmth, oxygen with CO₂, and artificial respiration are needed; then a stomach wash, first with water, preserving the stomach contents, then with potassium permanganate solution, 5 to 10 gr. to the pint with charcoal suspension. Gastric lavage is used, and repeated, even if the drug has been injected. Colonic lavage and rectal coffee may be employed. The time-honoured method of keeping the patient awake at all costs by mechanical means has been discarded as too exhausting. Respiratory stimulants, in particular nikethamide, should be given frequently and in full doses. Intramuscular injection of ephedrine and adrenaline may have an effect antagonistic to the opiates.

Apart from acute poisoning, an individual idiosyncrasy is sometimes seen, in particular in the very young and the very old, and in allergic persons. Such patients often vomit and they may show tremor, and even delirium and convulsions. It is dangerous to use morphine in cases of head injury, raised intracranial pressure, myxedema, and bronchial asthma.

COCAINE POISONING

Cocaine is obtained from the leaf of *Erythroxylum coca*; it is expensive and its habitués tend, therefore, to be wealthy psychopaths.

Ætiology.—The drug is most commonly met as a white powder, known to the underworld as *snow*, and taken as snuff; it can be injected or taken by mouth. A tolerance may be established, though not as high a one as in morphinism. Its chief delight is the speed with which it relieves fatigue; it temporarily enhances mental and physical vigour, being a true cortical stimulant.

Symptoms.—The patient suffers digestive disturbances and remarkable anorexia, dispenses with food and becomes emaciated. He complains of salivation and of formication or else a sensation of sand grains under his skin. There may be convulsions, hallucinations, delirium, or even mania. He is usually unpleasant to others, his behaviour alternating between exaltation and dejection, with a lowered moral tone and a proclivity to sexual excesses. He may have dilated pupils and sparkling eyes, tremor, nasal inflammation, ulceration or even perforation of the septum, or otherwise the tell-tale scars on the forearms of old sites of injection. He takes the drug for its stimulant effects and not to ward off withdrawal symptoms, which are slight.

Treatment.—Though the habit is not so compelling as morphinism, and withdrawal symptoms are less, the discipline of an institution is needed. The drug is abruptly stopped, and sometimes hyoscine by mouth is given as a temporary substitute.

ATROPINE POISONING

Atropine occurs in such solanaceous plants as *Atropa belladonna* (deadly nightshade) and *Datura stramonium*, together with hyoscyne and hyoscamine, the toxic actions of which are similar.

Ætiology.—Children are susceptible and apt misguidedly to eat the berries or seeds of these plants. Intoxication has occurred in using the drugs therapeutically, even in ophthalmology, but homicidal and suicidal cases have been few. Individual idiosyncrasy, revealed as a local reaction to atropine eye-drops, or as a general erythema and pyrexia, is not uncommon. The fatal dose is uncertain, but quantities of the order of $\frac{1}{2}$ to 2 gr. of pure atropine or 14 belladonna berries have been quoted.

Symptoms.—These appear quickly: there is a dry burning mouth, intense thirst, and difficulty with talking and swallowing; the skin is dry and flushed, vision is blurred, and photophobia present. The temperature rises and a state of excitement follows, suggesting acute mania or alcoholism, with obstreperous behaviour, disorientation, and hallucinosis. This picture may persist for some hours, or may in more severe intoxication give place to a stage of depression, when the victim is quiet and lapses into coma, dying from respiratory failure. Fatalities are rare.

When examined in the earlier stages, the patient has dilated fixed pupils, a red dry skin, tachycardia, pyrexia, and rapid respirations, perhaps a generalised erythematous rash; tremors and convulsions have been noted. Such signs may persist several days into convalescence, when there is mental confusion and loss of memory for recent events.

Treatment.—Use a locally acting emetic, and wash out the stomach with warm water and potassium permanganate 5 to 10 gr. to the pint. In the stage of excitement, morphine is to be avoided. Chloral hydrate, paraldehyde, or the rapidly acting barbiturates should be given. In the later depressive stage respiratory stimulants and oxygen may be needed. An injection of pilocarpine gr. $\frac{1}{10}$ to $\frac{1}{4}$ gives some relief to the dry mouth and ocular disturbances. Children should be especially watched at the height of the fever.

BARBITURATE POISONING

Synthetic derivatives of malonylurea, known also as cyclic ureides or barbiturates, are widely used as hypnotics.

Ætiology.—Few, if any, cases are reported of poisoning from normal therapeutic doses, and in 1931 barbiturates accounted for only 0.26 per cent. of suicides from all causes. The use of intravenous barbiturates for anaesthesia accounts for a proportion, as does the continuous narcosis used in psychiatric practice where the dosage needs to be unusually large. These conditions lead, as do accidental and suicidal cases, to a state of acute poisoning. The toxic dose of the compounds employed is usually between five and ten times the maximal therapeutic dose, and the lethal dose about 15 times, though a fatality has been reported from phenobarbitone only three times the therapeutic dose. Individual idiosyncrasy, kidney and liver disease, old age and toxæmic states increase the likelihood of poisoning, and can be taken as relative contraindications for using these drugs.

Pathology.—The skin is cyanosed and sometimes shows large vesicles. The lungs exhibit subpleural petechiæ, and are plum-coloured and cedematous, especially in their most dependent portions; purulent bronchitis and bronchopneumonia will be seen in all cases except those where the poisoning was very acute and the duration of coma correspondingly short. The brain is congested, softened and cedematous, sometimes showing evidence of a raised intracranial pressure. There is cloudy swelling in parenchymatous organs and fatty degeneration of the liver. The bladder is often full in spite of an apparent clinical oliguria, and the residual urine therein, together with the organs themselves, contains demonstrable barbiturate.

Symptoms.—Idiosyncrasy to the drugs is not uncommon, and the patient may complain of lassitude, depression, vertigo, nausea, and pains in the muscles. Allergic cutaneous manifestations, such as local swellings, bullous lesions and erythema, may be seen. There is no good evidence that barbiturates cause agranulocytosis.

Acute intoxication may present as follows: A state of lethargy with headache, vertigo, and ataxia, sometimes preceded by excitement, leads at first to deep sleep and later to prolonged coma. The pulse is rapid and weak, and the respiration slow and irregular: this, together with the late sign of a low blood pressure and general capillary dilatation, leads after some 24 hours to hypostatic bronchopneumonia, and the temperature then shows a sudden rise from its previously subnormal level. The pupils are variable, there may be an extensor plantar response, and the deep reflexes may still be present, even when the coma is deep. Oliguria is usual but suppression of urine is not often seen. Cutaneous blisters containing clear fluid sometimes appear. When death occurs, it is from respiratory failure in the early stages or from bronchopneumonia in the later.

Chronic barbiturate poisoning can result from repeated administration of the drugs which have prolonged action and which are thus cumulative, such as barbitone. The clinical picture is varied and perplexing, and comprises drowsiness, especially after meals, loss of memory, incoherent speech, and a state of confusion and disorientation. There is loss of weight and albuminuria; hæmatoporphyrinuria has been alleged but seldom found. Conflicting neurological signs are seen, and so are widely different skin eruptions, including morbilliform and scarlatiniform types.

Though it has been widely held that addiction is a danger to be expected, statistics give little support to the view, particularly when it is remembered how widely used the drugs are, and how often given to the psychologically unstable.

Diagnosis.—This is often difficult without circumstantial evidence in the history. It may have to be made by exclusion of other causes of coma. The urine, stomach washings, and cerebro-spinal fluid need to be examined chemically.

Prognosis.—The sooner treatment can be started the better, and the longer the patient is kept alive the better his ultimate chances. Coma may last for 7 days.

Treatment.—The immediate needs are warmth and stomach washing with warm water but not alkalis. Glucose, black coffee, and magnesium sulphate can be left in the stomach, and the washing repeated. Colonic lavage and lumbar or cisternal puncture also help in elimination, and should

388 DISEASES DUE TO PHYSICAL & CHEMICAL AGENTS

be repeated, as each attempt is known to remove more of the drug. Fluids and glucose by stomach tube or parenterally are required; as also are oxygen with CO_2 , and artificial respiration in some cases.

The specific antidotes are the respiratory stimulant and convulsant drugs. Strychnine can be given up to gr. $\frac{1}{2}$ every 4 hours, or nikethamide, with or without ephedrine, gr. $\frac{1}{2}$ intramuscularly. The best of all is picrotoxin intravenously, varying the dose and interval with the return of reflex activity. A 0.2 per cent. solution has been suggested, using as a maximum 1 mg. per minute until twitching is seen, when the dosage is reduced but continued for as long as necessary. Intravenous alcohol, 20 c.c. of a 30 per cent. solution every 4 hours, has been used successfully.

LEAD POISONING

1. ACUTE LEAD POISONING

This is rare. It usually results from swallowing a large dose of a soluble lead compound, such as lead acetate, which is also known as sugar of lead, from its sweetish taste. It has occasionally occurred when white lead has been mistaken for chalk and when lead chromate has been used to colour cakes or confectionery.

Pathology.—There are the usual signs of acute gastro-enteritis, and the stomach may be covered with a whitish grey deposit. The wall of the stomach and duodenum is sometimes thickened and softened, and erosions may occur from the local action of the lead compound.

Symptoms.—An astringent metallic taste is at once experienced, followed by a feeling of constriction in the œsophagus. A burning sensation and pain are felt in the epigastrium, and vomiting occurs. The vomit contains opaque whitish material, due to the precipitated albuminate of lead and lead chloride, formed by the action of the lead salt on the gastric contents. Blood may also be present. Severe colicky pains occur in the abdomen, with rigidity of the abdominal muscles. Pressure on the abdomen gives relief, and the patient may bend forwards for this purpose, or lie on his abdomen. The tongue is coated, and constipation usually occurs, but occasionally there is diarrhœa. The stools are dark coloured, owing to the formation of lead sulphide. Prostration and collapse occur if the abdominal symptoms are severe. There may be numbness or paræsthesia of the limbs, cramps in the legs, and partial suppression of urine. A blue line on the gums does not usually occur during the acute symptoms following a single dose of the poison.

The subacute form of poisoning follows the taking of repeated doses of a soluble lead compound. It may occur from repeated medicinal doses of lead acetate given to control diarrhœa. Abdominal colic is pronounced, and constipation severe. The other symptoms of acute lead poisoning occur, but are less intense in character. A blue line usually appears in the gums. If the teeth are frequently cleaned it is less likely to be formed. If the symptoms are of long duration lead palsy may result.

Diagnosis.—The diagnosis of acute or subacute lead poisoning can be confirmed by analysis of the vomit and feces for lead during life, and after

death by finding lead in the gastro-intestinal tract, liver, spleen and kidneys. Acute and subacute lead poisoning are rarely fatal.

Treatment.—If the case is seen within 3 hours of swallowing the poison the stomach should be washed out with water. Sodium sulphate or magnesium sulphate in half-ounce doses, dissolved in half a tumblerful of warm water, should be given every 4 hours until free purgation results, and this may be assisted by enemata, if necessary. The abdominal pain may be relieved by hot applications, repeated drinks of milk, and large doses of calcium lactate, five grammes (75 grains) three times a day. In severe colic by the slow intravenous injection of 15 c.c. of a 20 per cent. solution of calcium gluconate, or of 10 c.c. of a 5 per cent. solution of calcium chloride, it is possible to relieve the pain by the time the injection is over. If necessary this treatment may be repeated in 2 hours. Should it not be available a hypodermic injection of gr. $\frac{1}{16}$ atropine sulphate and gr. $\frac{1}{4}$ morphine sulphate may be given. For some weeks saline aperients and a high calcium diet should be given. The diet should contain 3 pints of milk daily, including milk puddings, junket and ice cream, together with butter, cheese and eggs.

2. CHRONIC LEAD POISONING

Synonyms.—Plumbism ; Saturnism.

Ætiology.—Apart from a few cases arising from accidental causes, chronic lead poisoning is of occupational origin. Lead is now encountered in more than 200 industries. In Great Britain there are more than 1500 workers in the lead industries and 150,000 painters. It has been known clinically for more than a hundred years that absorption of lead through the respiratory tract is very much more important than by the gastro-intestinal tract, and this view has since been amply confirmed by experiments on cats. In the prevention of dust and fume great success has been secured from the application of the Factories Acts. Idiosyncrasy is a factor in the development of lead poisoning, certain persons being more susceptible than others. Alcoholism also seems to be a predisposing cause. The sources from which lead is derived in chronic poisoning are very numerous, and they may be divided into 3 groups.

1. *Occupational risks.*—Men are exposed to danger in the smelting and tinning of metals, in vitreous enamelling, pottery glazing, shipbuilding, coach painting, plumbing and soldering, house painting, and in the manufacture of white lead, red lead, litharge, rubber, glass, cement, varnish, coloured pigments, linoleum and electric accumulators. Lead smelters are exposed to the fume and dust of furnaces and flues. Lead burners and chemical plumbers use oxy-acetylene, oxy-hydrogen, or oxy-coal-gas blowpipes in their work. The very high temperature of such flames constitutes a much greater risk than that faced by the domestic plumber who uses a spirit blowlamp. Painters are exposed when they rub down interior surfaces which have been painted with lead paint. The use of a blowlamp for burning off old paint is not without risk. A painter nowadays is very rarely exposed in mixing paint from the dry material, because it comes to him already mixed in oil. There is some risk to compositors who handle type metal, and to gasfitters who use red and white lead. It frequently happens that

390 DISEASES DUE TO PHYSICAL & CHEMICAL AGENTS

changes in methods or the appearance of new industries provide new causes of lead poisoning. This was the case with ship-breaking following on the scrapping of warships after the War of 1914-1918. In this industry the volatilisation of lead from the paint and red lead stopping on the armour plating occurs in the heat of the oxy-acetylene blowpipe flames used for cutting purposes. The great increase in the use of wireless receiving apparatus and motor cars has led to a greater number of cases of lead poisoning in electric accumulator factories. Sometimes the converse is true, and lead poisoning is found to show a remarkable diminution in a given industry. Thus, the substitution of machine methods for hand labour has abolished the disease among file cutters. The fall in the incidence of poisoning in coach painting is due to the enormous development of spray painting of motor cars with leadless cellulose paints.

2. *Accidental causes.*—Drinking water, especially if it is soft, or contains traces of acid derived from peat or dead leaves, may dissolve lead from lead pipes or cisterns and so give rise to poisoning. Beer or cider drawn from casks through lead pipes may become heavily contaminated. Aerated waters delivered from syphons with pewter or lead valves may give rise to poisoning. The lead glaze on earthenware vessels may be dissolved by vinegar, lemon juice, cider or home-made wine. The cooking of food in vessels tinned with solder containing lead may cause lead poisoning, especially if vegetable acids are present. Tinned foods sometimes contain lead from solution of the solder used in the tinning process. The lead foil used for wrapping sweets or food may contaminate them. Cosmetics, hair-dyes, and snuff weighted with litharge all have given rise to cases. Children with perverted appetites may chew the paint off their cots or toys. In Queensland, Australia, where the dry climate leads to flaking of painted surfaces, children have been poisoned owing to nail-biting, thumb-sucking and the habit of licking the raindrops off the painted balconies and roofs.

3. *Abortifacient uses of lead.*—Lead attacks the chorion epithelium, causing abortion in pregnant women. A like effect has been observed in animals in the proximity of lead works. Lead oleate plaster, known as diachylon, has been used in certain districts by pregnant women in order to cause miscarriage, the substance being swallowed in small portions rolled up in the form of a pill. To do this is very dangerous, for if miscarriage comes about death occurs later from lead poisoning. In consequence the sale of lead oleate has been restricted by placing it in Part I of the Poisons Schedule.

Pathology.—In chronic poisoning lead is stored in the skeleton, and under certain circumstances is released to attack (i) muscle, causing abdominal colic and lead palsy; (ii) the reticulated red cell, causing punctate basophilia (stippling) and anæmia; (iii) the chorion epithelium, causing abortion; and (iv) the brain, causing encephalopathy.

A good deal is known about the physico-chemical behaviour of lead in the animal body. It is probably transported in the blood plasma as the insoluble tertiary phosphate in the highly dispersed or colloidal form. At different stages of intoxication its distribution within the body varies somewhat. When absorption is slow it migrates to the skeleton, where about 95 per cent. is held without harm during the chronic stage of plumbism. If, however, large quantities of lead are being absorbed or are being liberated

from the bones, lead is distributed throughout the tissues and the percentage in the bones is reduced. Under these conditions acute symptoms of poisoning occur. It has been shown that the total amount of lead stored in the skeleton in lead workers varies from 0.2 to 0.8 gramme. This deposition of lead suggests a mechanism similar to that involved in the deposition of calcium phosphate. Repeated observations have shown that conditions which favour storage of calcium in the body also favour storage of lead. When conditions are unfavourable for the retention of calcium the excretion of stored lead increases.

In studies of lead excretion it is to be noted that normal persons with no occupational exposure to lead may excrete lead in the faeces and urine. This happens because lead is frequently present in the soil, and hence in vegetation and animal food. In normal persons the concentrations of lead may be 0.030 mg. per 100 gm. of blood, 0.027 mg. per litre of urine, and 0.28 mg. per 24 hours' sample of faeces. In toxicological analysis no satisfactory figures can be obtained unless specimens of stool and urine are collected for at least 3 days. A man working in a dusty lead industry, in addition to inhaling lead, may swallow repeated small amounts and pass lead unabsorbed in the faeces. The only proof of absorption, therefore, is to find lead in the urine. If specimens be taken some weeks after removal from exposure, the output may reach about 1 mg. for each 24 hours in the faeces and about 0.3 mg. in the urine. It is doubtful whether renal excretion exceeds this figure in any circumstances. Under effective treatment, however, the faecal excretion may rise to about 2 mg. in each 24 hours. It is necessary to emphasise that the presence of lead in the excreta is not necessarily proof that a lead worker is suffering from lead poisoning. Many such workers are insusceptible and have never suffered from any of the toxic episodes.

Lead palsy begins in the muscles, and fatigue determines the site of paralysis. The chemical explanation offered is that in regions of muscular activity the excess lactic acid which diffuses from the fatigued muscle cells combines with the lead phosphate in the blood to form lead lactate. As this soluble lactate comes into contact with inorganic phosphate at the surface of the muscle cells the lead is re-precipitated as insoluble phosphate, causing alterations in the surface permeability.

Studies of the blood in lead poisoning show that the stippled red cell arises from the reticulocyte, and that the attack occurs peripherally and not in the marrow. Blood films can be prepared showing all stages between stippled fragments and typical reticulum. Stippled cells are never found in the bone marrow in lead poisoning. The presence of punctate basophilia in the blood is not, of course, a specific sign of lead poisoning. It is seen in pernicious anaemia, in leukaemia, in the anaemias of carcinomatosis and in pneumonia in infants. Its occurrence in these various conditions is relatively rare and slight as compared with the frequency and intensity of its appearance during plumbism. For this reason the demonstration of stippling of the red cells in the blood has come to be considered as almost definite evidence of absorption of lead. It is not an absolute indication of the severity of lead poisoning, but it often runs parallel to the state of health. If on examination of the films its presence is detected in a sufficiently large number of fields of the microscope, further exposure to lead in the patient concerned should be prevented immediately. Punctate counts are of value

392 DISEASES DUE TO PHYSICAL & CHEMICAL AGENTS

in the prophylaxis of plumbism among lead workers and are essential in the adequate hygienic control of lead processes.

Except in cases of encephalopathy, which are now very rare, chronic lead poisoning is not a direct cause of death. In 1851 Garrod pointed out that gout was quite common among lead workers in Great Britain, but there is nothing to show that the occurrence of these two conditions in one patient was other than fortuitous. Chronic lead poisoning produces no characteristic post-mortem changes. Neither animal experiments nor the mortality figures of the Registrar General offer any evidence that lead significantly predisposes to hypertension or Bright's disease.

Clinical History.—The past occupations of the patient should be inquired into, for latent lead poisoning is well known to occur. The present occupation is obviously of great importance and the exact details of the work he does should be elicited from the patient himself. Often a man's occupation does not at first sight suggest that he is exposed to compounds of lead. A man describing himself as a fitter may be exposed to dust or fume of lead; this fact is only elicited in answer to a leading question. The occupation of a cooper becomes dangerous when the barrels worked upon have contained compounds of lead. Vitreous enamellers working, for example, on baths, sift a powder containing lead silicate on to the bath which has been heated in a furnace. They sometimes use a compressed-air apparatus which forces the enamel through a sieve. In the electric accumulator trade pasters fill the spaces in accumulator plates with a paste containing litharge and red lead. Colour manufacturers grind colours into a fine powder under edge runners with the necessary production of much dust. Amongst other things they grind lead chromate and red lead. A slate mason may construct storage tanks by fixing together slabs of slate with materials containing oxides of lead. A bullion refiner may use a process in which he adds lead to refinable silver in a furnace and taps off molten litharge. A rubber compounder adds oxides of lead to crude rubber in preparation for vulcanisation. A girl describing herself as a perambulator maker may be employed painting the body work of perambulators and then rubbing down the surface with dry sand-paper. An embroidery worker sometimes stencils materials by dabbing on the pattern commercial white lead instead of chalk.

Symptoms.—The toxic episodes resulting from the absorption of lead are colic, palsy, anaemia, and encephalopathy. The blue line on the gums is a sign of absorption and not of intoxication.

Lead colic.—This is the most common and dramatic of the acute manifestations of plumbism. It is ten times as common as lead palsy. An attack of colic is preceded by several days of constipation. The pain is of a tearing or griping nature and of variable intensity. It is situated around or below the umbilicus, and the patient often indicates where it is by spreading both hands widely over the abdomen. While suffering from colic the patient is cold, pale, and often drenched with perspiration. He commonly bends over and may writhe about the bed in intense pain. Examination shows a scaphoid abdomen, held tense, but showing no rigidity. Vomiting frequently occurs at the onset of the pain.

Lead palsy.—This does not belong to the category of polyneuritis, either clinically or pathologically. It is in the first instance a muscle disease. Fatigue plays a most important part in determining the sites attacked.

Where the muscle palsy is neglected the lead attacks the motor nerve fibres and ultimately the anterior horn cells of the spinal cord. (See also p. 1816.) Paralysis does not appear to be closely related to length of exposure. It may develop during the first month of work, or only after many years' exposure. The commonest form is the well-known wrist-drop which begins usually in the right hand and later becomes bilateral. The palsy first appears in the long extensors of the middle and ring fingers. It spreads to the other fingers, and then to the long extensors of the wrists. The supinator longus, and usually the long abductor of the thumb escape. The brachial type of paralysis involves the deltoid, biceps and supinator longus, but it is very rare for this to occur without wrist-drop. A third form of lead palsy in which progressive atrophy occurs of the thenar and hypothenar eminences, together with the interossei, used to be common in the left hand of file-cutters. In view of the theory that fatigue plays an important part in determining the site of lead paralysis, this observation is of great interest, for in their work file-cutters not only used particularly the muscles mentioned but placed the greatest strain upon the left hand. The substitution of machine methods for hand labour has abolished lead poisoning amongst file makers. Lead palsy rarely occurs in the lower limbs, but when it does so it affects the extensors of the toes, giving rise to foot-drop.

The anæmia.—Secondary anæmia with basophil punctation (stippling) of the red cells is characteristic. It is usually mild, and it is rare to find less than 3 million red cells per c.mm. Because of the loss of circulating red cells there is compensatory regeneration of erythrocytes, with a high reticulocyte count.

Encephalopathy.—Most of the ancient writers speak of the frequent occurrence of convulsions in lead poisoning, but fortunately with the improvement of industrial conditions the incidence of lead encephalopathy has progressively decreased until to-day cases are rarely seen. It is the most dramatic manifestation of lead poisoning, and is always of serious prognostic significance. In severe cases of plumbism the patient is dull, with poor memory, and inability to concentrate. The onset of encephalopathy is nevertheless sudden, usually with epileptiform convulsions. It may be divided into three groups—convulsive, comatose and delirious. The lymphocyte count in the cerebrospinal fluid may reach 100 per c.mm.

The lead line.—The lead line consists of fine granules of pigment arranged in the form of a dark blue stippled line within the tissues of the gum about a millimetre from the border of the teeth. It is more marked round infected or dirty teeth, and is occasionally found on the mucosa of the cheek opposite such teeth. Despite the pigment lying within the tissues, careful cleansing of the mouth and teeth often causes it to disappear. Its clinical significance should be clearly recognised. It is an indication of absorption and not of intoxication. Its intensity and size provide a rough guide to the duration and severity of exposure to lead.

Diagnosis.—Opinions differ widely as to what is necessary for the diagnosis of lead poisoning. Constipation and slight stippling of red cells are insufficient; neither a blue line on the gums nor detection of lead in the urine can be taken as proof of poisoning, for the patient may be insusceptible. Where a worker is exposed to risk, a diagnosis of lead poisoning can be made before the occurrence of a toxic crisis. A falling hæmoglobin

percentage, with or without a rising punetate basophile count, raises a suspicion that absorption is passing into poisoning. The suspicion becomes a certainty when these changes are marked or progressive. The urine should be collected for at least 3 days and examined for lead. There is a danger of wrongly attributing to lead poisoning any symptoms which may occur in persons exposed to lead. Acute appendicitis, chronic gastric or duodenal ulcer, and carcinoma of the stomach occur in lead workers as they do in others. They must be carefully differentiated from colic. Equally a lead worker can suffer from pernicious anæmia or secondary anæmia due to piles, melæna or hæmatemesis. It is important to remember that lead poisoning has to be severe before the red cell count drops below 3 million. In industrial cases the blue line is unlikely to give rise to confusion. A similar phenomenon is commonly seen in patients under treatment with bismuth preparations given intramuscularly. The differential diagnosis of lead palsy should give rise to no difficulty, especially as the changes are entirely motor. In a case of peripheral neuritis in which there are motor, sensory and pigmentary changes, the possibility of arsenic poisoning must be considered. Litigation hysteria is all too common in the lead worker. The manifestations include hysterical spasm of the hand and arm, weakness of various movements, including the flexors of the wrists and fingers, glove and stocking anæsthesia, complete hemi-anæsthesia and hysterical aphonia. Such symptoms are rarely alleviated until legal proceedings are completed.

Treatment.—PROPHYLACTIC.—The treatment of chronic lead poisoning is essentially preventive. Food and drink containing organic acids should not be stored in earthenware vessels glazed with lead. Supplies of soft water for drinking purposes when delivered through lead pipes should be artificially hardened by the addition of calcium salts. Lead pipes used to convey beer or cider from the cellar to the bar engine in public houses must be lined with tin. Children's toys and cots must never be painted with lead paint. The law must restrict the sale of lead oleate and forbid the addition of litharge to snuff in order to make it heavy.

In industry less than 100 cases of lead poisoning were notified in 1933 as compared with more than 1250 in 1889. In Great Britain preventive measures are carried out with such success that the majority of cases of lead poisoning are mild. It is unusual to-day to meet with a case either of severe colic or of extensive palsy, and encephalopathy has been abolished. The most important single measure of prophylaxis is the prevention of dust and fume. In achieving this, great success has been secured from the application of the principle upon which Sir Thomas Legge always laid so much stress, namely, to apply methods entirely external to the workman—methods over which he himself can exercise no control. One such method is exhaust ventilation applied through hoods at the point of origin of dust or fume. Benches, tools, floors and walls must be spotless, often at the expense of the constant vigilance of several good foremen. No scrap lead nor dry white lead should be handled unless it has been thoroughly soaked with water from a hose. As far as possible mechanical means, such as cranes, rails, hoists, covered conveyors and hoppers, and automatic packing machinery must be substituted for hand carriage.

Fortunately about 50 per cent. of the white lead manufactured in Great Britain is never handled in the dry state. It is made by the stack process

and leaves the stack in a wet state to be converted into an aqueous paste, mixed with linseed oil, and made into an oily paste in automatic closed-in machines without dry grinding. Since a white-lead worker may handle in the course of a day at least as much white lead as a painter handles in a year, the value of this wet pulping method will at once be realised. In the manufacture of litharge and red lead it is impracticable to use wet methods, and it is therefore necessary to use machinery designed to minimise dust. Since 1927 it has been illegal for a painter to rub down by dry methods any indoor structure previously treated with lead paint. Dust can be avoided by using a damp rubbing down process for lead painted surfaces. Waxed sandpaper which the workman dips repeatedly in a bucket of water has made this possible.

In addition to cleanliness in the workplaces, personal cleanliness is of the first importance. Cloak-rooms, washing-rooms, mess-rooms, baths, nail-brushes, towels and soap must be provided. The hands should always be washed before eating and the work-people urged to take a warm bath frequently. The bringing of food or drinks into the work-rooms should be forbidden, and so also should smoking at work. Medical examination of the workers exposed must be carried out periodically. At present there is no biological test by which to select workmen immune to the toxic effects of lead. Since they have been found unduly susceptible, it is necessary to forbid the employment of pregnant women and of all persons under 18 years of age in the potteries and other lead trades.

In the prevention of lead poisoning a diet of high calcium content plays its part. In lead works in Great Britain it has for many years been customary to provide the workmen free of cost with a glass of milk each morning. This is empirical treatment of considerable merit, anticipating as it did by many years the discovery that a high calcium intake assists the storage of lead in a harmless form in the bones. Workers should, in addition, take aperients regularly. Any worker who develops one of the toxic effects of lead has thereby proved his susceptibility, and ideally he should never again work in any department of a lead works.

CURATIVE.—Effective new methods for the treatment of lead poisoning were published by Aub and his collaborators in 1925. They found that a positive calcium balance favours the storage of lead as a harmless deposit in the bones. In cases of lead poisoning showing toxic symptoms the diet should contain 3 pints of milk daily, including milk puddings, junket and ice-cream, together with butter, cheese and eggs. In addition large quantities of calcium lactate, 5 grammes (75 grains) three times a day may be necessary. As soon as the calcium intake is sufficient the symptoms will cease. In the presence of any acute toxic episode no attempt should be made to increase the elimination of lead; so much is already circulating that it is safer to encourage further storage.

Lead colic.—Colic should be treated by the local application of heat, pressure and moisture. The bowels should be moved as early as possible by means of enemata of olive oil and warm water, and by the internal administration of magnesium sulphate along with belladonna and carminatives. Treatment by a high calcium diet usually brings relief within 2 days. The relief of lead colic by calcium therapy involves more than the ability of calcium to favour storage of lead. Since the pain is due to violent peristalsis

behind a contracted tonic ring of intestine, the anti-spasmodic effect of calcium salts on involuntary muscle is beneficial. In severe cases, by the slow intravenous injection of 15 c.c. of a 20 per cent. solution of calcium gluconate, or of 10 c.c. of a 5 per cent. solution of calcium chloride, it is possible to relieve the pain by the time the injection is over. The patient feels hot and flushed, and may vomit. The effect upon the pain is striking, and is superior to that of any other treatment. If necessary the injection may be repeated in 2 hours. Should such treatment not be available a hypodermic injection of $\frac{1}{6}$ grain atropine sulphate may be given.

Lead palsy.—During the development of lead palsy, a high calcium diet should be used to favour storage of lead. Massage, electrical treatment and strychnine are useful. In the early stages the hands, when affected by wrist-drop, should be supported on splints. The paralysed muscles may be stimulated by an induction coil, with or without a water bath, but over-stimulation must be avoided since it induces fatigue, and so does harm.

Encephalopathy.—Lead encephalopathy should be treated by lumbar puncture. A high calcium diet should be given together with large quantities of milk and calcium lactate.

Elimination of lead.—In cats experimentally poisoned with lead, acute symptoms may develop during starvation, and at necropsy lead is found distributed more generally through the body than is typical of the chronic condition. This suggests that during starvation acidosis sets lead free from the bones. The reason for this is the conversion of the tertiary phosphate of lead into the secondary phosphate which is one hundred times more soluble. Hence the ingestion of acid as a method of treatment probably serves to liberate lead from the skeletal stores by converting it into a more soluble salt.

Aub at first produced acidosis by the use of phosphoric acid, but he found it more satisfactory to give large doses of ammonium chloride. Chronic lead poisoning may be treated by the cautious administration of this substance in doses of 1 gramme (15 grains) given in a glass of water eight or ten times daily for 3 weeks at a time. The dose should be reduced if loss of appetite and headache appear, for these symptoms indicate the limit of tolerance to such treatment. In no case should ammonium chloride be used until a few weeks after the acute toxic episode has passed. A diet with a very low calcium content facilitates release of lead from the bones. In such a diet all milk, milk products, green vegetables and eggs are omitted. It may contain meat, liver, chicken, potato, peas, rice, tomato, banana, apple, lemon, tea, coffee, sugar, honey, salt and pepper. All bread must be prepared without milk. Butter fat must be substituted for butter. This is prepared by melting butter in hot water and skimming off the butter fat. In those places where the water supply is hard, vegetables should be cooked in distilled water and all drinks made up with it.

Since it would doubtless require several years, it is useless to attempt the elimination of all the lead stored in the body. It is desirable to eliminate only the most readily mobilised lead. In prolonged observations the results indicate that after a certain point elimination of lead becomes progressively more difficult. When this stage is reached it is more practicable to favour its retention in the bones by maintaining a positive calcium balance. Thus after 3 weeks' treatment by a low calcium diet and ammonium chloride, there should be a rest period of a week with normal diet and abundance of

milk to correct the calcium deficiency. Treatment to accelerate elimination should then begin again.

Potassium iodide has been employed by clinicians since 1844. It is not as effective as treatment by acidosis, but has the advantage of ease of administration. The dose should be increased from 5 grains three times a day to 15 grains three times a day. Its physiological effectiveness appears to diminish progressively after the first few days of treatment. Neither ammonium chloride nor potassium iodide should be used in the presence of nephritis or of toxic symptoms. Should any toxic episode appear during the use of ammonium chloride or potassium iodide, these drugs must be stopped and a high calcium diet at once used to favour the storage of lead. Occasionally cases of latent lead poisoning occur, that is to say, cases in which symptoms have been precipitated by various forms of treatment long after exposure to lead has ceased. Thus a lead line or wrist-drop may follow upon the use of potassium iodide as an expectorant.

It is necessary to emphasise the difference between the use of agents which assist excretion of lead and those which assist its storage. The acidosis method of lead elimination is so potent that its use during colic or any other toxic episode might prove fatal from the further mobilisation of lead. It is scarcely necessary to add that such treatment should never be used as an excuse for negligence in enforcing all the known measures for the prevention of exposure and absorption.

3. TETRA-ETHYL LEAD POISONING

Tetra-ethyl lead is an organic lipid-soluble liquid readily absorbed through the skin and respiratory tract. It is added to petrol in proportions up to 1 in 1260 as an antidetonant. In 1923, when it was first manufactured in the United States, 149 cases of encephalopathy occurred in men employed on three separate plants. Within 17 months 11 deaths were reported. Much excitement and alarm were caused, and this led at first to the prohibition of the manufacture. The men affected suffered from restlessness, talkativeness, ataxia, insomnia and delusions. There were no paralyses nor convulsions, but the condition terminated with violent mania, the patient shouting, leaping from bed, and smashing furniture. By meticulous attention to detail it is possible to manufacture tetra-ethyl lead and to blend it with petrol without risk to the worker. Even so, ethyl petrol should not be used for cleansing the skin and to prevent this it is marked by a dye. There is little need for apprehension as to the possibility of the poisoning of garage and aircraft workers by lead from the exhaust gases of petrol engines.

ARSENICAL POISONING

Arsenic is the most important of the irritant poisons, and owing to the almost tasteless property of many of its compounds and preparations it is perhaps the commonest poison used for homicidal purposes. At one time it had a reputation as a cosmetic, and was added to face powders and skin lotions. It is practically never used now for such purposes.

Occurrence.—*White arsenic*, i.e. arsenious acid, or arsenious anhydride, As_2O_3 , is the most important of the compounds of arsenic. It occurs in the

398 DISEASES DUE TO PHYSICAL & CHEMICAL AGENTS

form of a white powder, or in lumps like glass or porcelain (vitreous arsenic). The powdered form resembles powdered sugar or flour, and when mixed with food is tasteless. It is slightly soluble in cold water, an ounce of cold water dissolving from a half to one grain. In boiling water it is twelve times more soluble, from 6 to 12 grains dissolving in an ounce. Alkaline solutions readily dissolve arsenic. If white arsenic is sold to the public the law requires that it should be mixed with soot or indigo to colour it. It is used in the composition of sheep dip, arsenical soap and rat poison.

Metallic arsenic is a black powder. It is very poisonous, and is used for killing flies. *Copper arsenite* (Scheele's green) is bright green in colour, and used to be employed for colouring wall-paper, toys, floorecloths and fabrics. Its use for such purposes has fortunately been abolished. *Arsenious sulphide*, or orpiment, is a yellow powder known as king's yellow. *Arsenic acid*, in the form of its potassium and sodium salts, which are white, crystalline and soluble in water, is used as a fly poison and in the manufacture of aniline dyes. Injurious effects, such as local skin eruptions, are sometimes caused by the action of the arsenical compound present in the dye of stockings. *Sodium arsenite*, in the form of solutions of arsenic in caustic soda, or in sodium carbonate, is commonly used for the preparation of fly-papers, weed-killer, preservative for wood and arsenical sprays for fruit trees. Weed-killer and some of the so-called preservatives for wood contain from 20 to 40 per cent. of arsenic in solution, and are intensely poisonous. Both weed-killer and the arsenic obtained from fly-papers have been used for homicidal purposes.

Arsenic in food.—Accidental contamination of food with arsenic, or its preparations, such as weed-killer, has occurred. Arsenical pigments have been used for colouring sweets and cakes, with fatal result. A serious outbreak occurred in 1900, owing to the contamination of commercial glucose by arsenic. Sulphuric acid prepared from pyrites and containing a considerable amount of arsenic had been used in the process of the conversion of starch into commercial glucose, so that the latter became impregnated with arsenic. The use of the glucose in the manufacture of beer led to the outbreak of arsenical beer poisoning which occurred in Manchester and the North of England. A Royal Commission investigated the cause of this epidemic, and made safeguards against the further occurrence of such poisoning. Limits of the amount of arsenic permitted in food-stuffs were fixed at $\frac{1}{100}$ gr. per gallon for liquids and per pound for solids.

Arseniuretted hydrogen, or arsine, is a very poisonous gas. It is produced when hydrogen is generated in the presence of a compound of arsenic, for example, in the action of mineral acids on impure metals, as occurs in metal pickling and in balloon filling.

Dimethylarsine is a poisonous gas produced by the action of moulds upon certain compounds of arsenic.

The *arsenobenzene* derivatives which are extensively used in the treatment of syphilis and other diseases, may give rise to fatal poisoning.

The varieties of arsenical poisoning are—(1) acute, (2) chronic, (3) arseniuretted hydrogen poisoning, (4) dimethylarsine poisoning, and (5) poisoning by arsenobenzene derivatives.

1. ACUTE ARSENICAL POISONING

Pathology.—The stomach contents usually contain much mucus, which may be blood-stained. The signs of gastro-intestinal inflammation are present. The mucous membrane is swollen, red and congested, and petechiæ are usually well marked. The redness is most marked on the summits of the rugæ. When the arsenic has been taken in solid form, white or pigmented particles may be seen on the mucous membrane of the stomach. The duodenum is red and congested, and petechiæ may be present; there is usually marked yellow staining, due to altered bile. The small intestine may show similar signs to the duodenum, but these diminish on passing downwards. The liver, kidney and other organs may show cloudy swelling. In fatal cases the arsenic absorbed into the tissues has a preservative action, and tends to delay putrefaction.

Symptoms.—When the poison is taken by the mouth, if diluted well or mixed with food, no taste or pain in the mouth or throat is experienced. The symptoms begin within an hour if the stomach is empty; but may be delayed if the stomach is full, and if the poison is in the solid state there will be further delay. A burning pain occurs in the epigastric region, and nausea and vomiting usually follow. The vomit will contain any food present in the stomach, and there is often much mucus. Bile is usually present, and sometimes streaks of blood. As the poison is passed on to the intestine, abdominal pain, of a griping or colicky type, and usually diarrhœa occur. The stools are watery, and may contain flakes of mucus. The continued vomiting and diarrhœa cause exhaustion, faintness and collapse. Cramps in the legs may occur, but are not a constant symptom. In a severe case restlessness, stupor and coma develop, and death follows shortly. Death in an acute case may occur within 24 hours, or may be delayed for 3 days or more. When several repeated doses are taken, so that the symptoms are protracted over several days, some of the symptoms of chronic arsenical poisoning may develop.

Fatal dose.—Two grains of arsenic have caused death in a woman, and this is accepted as a possible fatal dose.

Treatment.—The stomach should be washed out, and afterwards as an antidote freshly precipitated ferric hydroxide may be given. This is prepared by adding to half a tumblerful of water half an ounce of tincture of perchloride of iron and also sodium carbonate solution till the mixture is distinctly alkaline. Pain is relieved by the hypodermic injection of morphine. Demulcent drinks should be given, and the usual stimulant treatment for collapse.

2. CHRONIC ARSENICAL POISONING

Symptoms.—The gastro-intestinal symptoms—nausea, abdominal pain, vomiting and diarrhœa—are not prominent, and even may be absent. The tongue is often covered with a silvery white fur. General malaise, anorexia and anæmia are usually present. Irritation of the throat and huskiness of the voice, due to the presence of pharyngitis and laryngitis, result. Conjunctivitis may occur, with redness and swelling of the eyelids. Skin

affections, such as erythema, herpes, pigmentation, or erythromelalgia, are commonly to be noted.

If taken medicinally, or otherwise, over a long period, arsenic produces a finely mottled general brownish pigmentation of the skin. It affects principally the covered parts. The mucous membranes are not involved. Thickening of the epidermis of the soles and palms, and irregular thickening of the nails are present in long-standing cases. In some cases salivation is a marked feature, paroxysmal attacks of excessive secretion of saliva occurring. Symptoms of multiple neuritis are likely to develop, and these affect both the upper and lower extremities.

Long-continued poisoning causes anæmia, peripheral neuritis, progressive wasting and weakness, death resulting from exhaustion and cardiac failure, ascites and general œdema occurring towards the end. The urine, fæces, the distal portions of the hair and the nails contain arsenic, its detection serving to confirm the diagnosis during life. The tests for arsenic will be found in works on toxicology. It must be remembered that in cases of suspected arsenical poisoning the diagnosis can always be made with certainty by an analysis of the urine, vomit and fæces, and these should always be taken for examination, the tests being made by an expert toxicologist.

It is important to remember that acute arsenical poisoning, where a large dose is taken, may (if the patient recovers from the acute attack) be followed by symptoms of chronic arsenical poisoning. Severe peripheral neuritis may follow acute poisoning from a single dose of arsenic.

Treatment.—This consists in the prevention of the absorption of arsenic in any way, and eliminative and stimulant treatment.

3. ARSENIURETTED HYDROGEN POISONING

Ætiology.—Arseniuretted hydrogen is a poisonous gas which is not manufactured in industry but is evolved as an accidental by-product in certain processes. The majority of cases have been due to the use of acids and metals contaminated with arsenic. The occupations concerned are the extraction of mineral ores, pickling and galvanising of metals, cleaning of acid tanks, the manufacture of hydrogen and its use in ballooning, and the making and charging of accumulators. Poisoning may arise from the action of water upon metallic arsenides. Cases have also occurred when ferrosilicon, a substance used for hardening steel, has come in contact with water, when a mixture of arseniuretted and phosphoretted hydrogen is evolved.

Pathology.—The gas is inhaled and acts at once by hæmolyzing the red cells within the vessels. Hæmolytic jaundice and anæmia follow. Death may occur from anuria if the renal tubules become blocked with hæmoglobin. Degenerative changes in the cells of the liver and kidneys, and numerous petechiæ on the mucous and serous membranes, are to be noted.

Symptoms.—Malaise, headache, dizziness, shivering and hæmoglobinuria occur within a few hours. Within 24 hours there is nausea, vomiting, and jaundice, and by the third day anæmia in which the red cell count may fall below 1,000,000 per c.mm. Delirium, stupor and coma precede death.

Diagnosis.—Mild cases are often mistaken for food poisoning. The sudden onset of hæmoglobinuria and jaundice at once suggests inquiry into a man's occupation.

Prognosis.—Mild cases quickly recover. The mortality rate is 30 per cent.

Treatment.—Workshops should be adequately ventilated and processes known to be risky should be forbidden in confined spaces. Sometimes a breathing apparatus suitable for use in irrespirable atmospheres must be employed. Such an apparatus consists of an oro-nasal mask with tube connection to the outer atmosphere. The wearer draws fresh air through the tube by his inspiratory efforts and expels the expired air through a valve in the mask.

4. DIMETHYLARSINE POISONING

The use of Scheele's green (cupric arsenite) in the preparation of artificial flowers and wall-papers has now only historical interest, because aniline colours have almost entirely taken the place of arsenic in these processes. The mould *Penicillium brevicaulis* growing in the paste behind wall-papers in damp rooms liberated dimethylarsine. The same process may occur in damp houses where coke breeze containing arsenic forms a constituent of the plaster on the walls. The use of concrete blocks containing this substance and the deliberate addition of arsenious oxide to cements to increase their rates of hardening are clearly undesirable. The symptoms of poisoning are coryza, conjunctivitis, gastro-enteritis and tinglings in the extremities. Some cases are fatal.

5. POISONING BY ARSENOBENZENE DERIVATIVES

Arsenobenzene derivatives, such as arsphenamine, neoarsphenamine, and sulpharsphenamine, are usually administered intravenously. After a full dose (0.6 g. arsphenamine, 0.9 g. neoarsphenamine) nausea, a slight rise of temperature, with perhaps vomiting and a little diarrhoea, may occur in the following 24 hours, after which the patient is quite well. Occasionally severe vomiting and diarrhoea, with furred tongue, erythematous rash and acute gastro-intestinal symptoms, may follow. In such cases it is probable that there has been some decomposition in the solution administered, the symptoms resembling those of acute arsenical poisoning. This type of poisoning is rare. Arsphenamine and allied compounds, especially after the administration of successive doses, sometimes cause such damage to the liver that extensive necrosis occurs and toxic jaundice develops, which may be fatal.

When dangerous toxic symptoms occur after arsphenamine, they are usually of the following type: After an interval of 2 or 3 days, vomiting and restlessness, delirium, stupor, often with twitchings of muscles, convulsions and Cheyne-Stokes breathing, occur. Sometimes jaundice is observed. Coma develops, with suppression of urine, and death may occur within 48 hours. The symptoms are the result of impairment of the function of the liver and kidneys. The prognosis is very grave.

Treatment consists in the administration of alkalis by the mouth and bowel, and saline per rectum. Glucose, milk and fruit juices should be given freely.

In order to protect the liver, dextrose and calcium lactate may be given a few hours before administering arsphenamine compounds. It should also be borne in mind that if full doses are employed, a fortnight is required for

the excretion of the drug, and that interval should elapse between the doses. Where submaximal doses are used, *c.g.* 0.4 g. arsphenamine or 0.6 g. neo-arsphenamine, weekly injections are often administered, but after a few doses an interval of 3 or 4 weeks should be allowed to avoid a cumulative effect.

See also Toxic Effects of Arsphenamine Remedies, pp. 221-225.

MERCURIAL POISONING

1. ACUTE MERCURIAL POISONING

This usually arises from the absorption of mercuric chloride, also known as corrosive sublimate (HgCl_2), which is largely used in medicine as a disinfectant or antiseptic. Binioidide of mercury has similar uses. Both are usually purchased in the form of tablets ready for solution in a required amount of water. Acute poisoning generally occurs from the taking of the poison by the mouth, but it may also arise from the use of mercuric compounds in solution as uterine or vaginal douches. Calomel (mercurous chloride), even if taken in large doses, does not give rise to the same degree of acute poisoning, owing to its insolubility. The writer has met with 2 cases in which over 100 grs. of calomel were taken with suicidal intent, and beyond some vomiting and diarrhoea, little harm resulted.

Symptoms.—If mercuric chloride is swallowed in tablet form there is risk of local corrosion and perforation of the stomach, with rapidly fatal result.

When taken in solution, or in tablet form with water, or on a full stomach, an acrid metallic taste is experienced, followed by a sense of constriction in the throat. A hot burning sensation occurs in the mouth and œsophagus. Acute abdominal pain and vomiting take place. The vomit contains much slimy mucus and often blood. Diarrhoea and tenesmus occur. Collapse is associated with these early symptoms. The mouth and pharynx may show signs of local damage, such as white swollen patches, which may be followed by sloughing. Unless the poison is quickly removed by gastric lavage the dangerous sequelæ of absorption rapidly follow.

The two chief dangers of acute mercurial poisoning are: (1) suppression of urine and uræmia, due to the toxic action of the poison on the renal epithelium causing cloudy swelling, necrosis and loss of function; and (2) ulcerative colitis, the result of the action of the poison on the mucous membrane of the colon, whereby extensive necrosis and sloughing occur. Suppression of urine follows the absorption of the poison, and urine secretion may almost entirely cease. The cessation of renal secretion is followed by a rapid rise in the blood urea, and after 4 or 5 days dangerous symptoms of uræmia, vomiting, stupor, delirium, coma and convulsions set in, which are generally rapidly fatal. The ulcerative colitis begins about 24 hours after the intake of the poison, and is associated with profuse diarrhoea, and the passage of sloughs and shreds of necrotic mucous membrane and blood. The colitis may be caused as the result of absorption of the poison into the blood stream apart from its direct local action on the colon. Death may occur from exhaustion, and absorption of toxic products from the raw surface of the bowel.

Acute mercurial poisoning is always accompanied by a very severe stomatitis, which begins within a few hours. The breath is foul, the mucous membrane becomes ulcerated, the teeth may become loose and necrosis of the alveolus occur.

Five grains of mercuric chloride is a fatal dose for an adult, unless the poison is removed by gastric lavage within an hour or two.

Treatment.—Immediate gastric lavage should be employed. Afterwards, white of egg and milk should be given freely. The collapse, suppression of urine, ulcerative colitis and stomatitis are other symptoms treated by the appropriate methods for such conditions.

2. CHRONIC MERCURIAL POISONING

Ætiology.—This condition occurs chiefly amongst workers in the metal, or amongst those who are constantly brought into contact with compounds of mercury; for example, those engaged in mining and separation of the metal, *e.g.* at Almaden in Spain, at Idria in Austria, and at the mines in California, China, Peru and the Ural Mountains. Mirror makers, thermometer and barometer makers, and those engaged in the manufacture of chemical and electrical apparatus in which metallic mercury is used, are exposed to risk. Those engaged in the frequent handling or grinding of mercury compounds are sometimes attacked. It must be remembered that mercury is volatile at ordinary temperatures, and those working in ill-ventilated rooms where mercury is exposed are liable to attack. Cases have been recorded of chronic mercurial poisoning from the amalgam in tooth stoppings, and from sojourn in a respiration apparatus fitted with mercury air-valves. The nitrate of mercury is used in the felting of fur, and hatters' furriers are liable to chronic poisoning unless they are properly protected. The condition may result from the continued administration of calomel or blue pill, from the inunction of mercury ointment, or from the prolonged use of mercurial vaginal douches.

Symptoms.—Dyspepsia, anæmia, general cachexia, with loss of weight and strength, occur. Sometimes a blue line is seen on the gums if the teeth are neglected. Stomatitis is one of the most constant symptoms; increased salivation and marked fetor of the breath occur, and are associated with tenderness of the gums and looseness of the teeth. Colitis, often of an ulcerative type, may result from chronic mercurial poisoning. It is a dangerous complication and difficult to treat. Skin rashes of an erythematous, eczematous or pustular type have occurred. Albuminuria is occasionally found. Glycosuria has been described, but it is rare. Tremor, affecting the muscles of the tongue and face, the arms and hands, and later the legs and trunk, occurs. It is of a fine type, but may be interrupted every few minutes by coarse shaking movements, known to the layman as the "hatters' shakes." The severe mental symptoms known as erethism have been rare since silver took the place of mercury in mirror making. The man affected is easily upset and embarrassed, loses all joy of life, and lives in constant fear of being dismissed. He has a sense of timidity and may lose self-control before strangers. He may be obliged to give up work because he can no longer take orders without losing his temper. Drowsiness by day, depression, loss

404 DISEASES DUE TO PHYSICAL & CHEMICAL AGENTS

of memory and insomnia may occur but under modern industrial conditions hallucinations, delusions and mania are rare.

Diagnosis.—This is made by the history and symptoms; but it should be confirmed by analytical tests. Mercury is excreted in small amounts in the faeces. The greatest care should be taken that no mercurial preparation is being administered medicinally during the test. The faeces are collected, and the organic matter destroyed by treatment with hydrochloric acid and potassium chlorate. The resulting solution is submitted to electrolysis, and the mercury present is deposited on a gold kathode, from which it may be dissolved and submitted to the usual chemical tests.

Treatment.—In the manufacture of clinical thermometers and in laboratories where mercury is handled extensively, the benches must be covered with a smooth and impervious surface sloping in such a way as to drain the mercury into a suitable receptacle at the lowest point. The walls and floors should be of impervious material, and the floor cleansed at the end of each day's work. Thermometers must not be filled without suitable exhaust-ventilation for the removal of mercury vapour. Overalls, mess-rooms, and washing facilities are provided. The mouth and pharynx are frequently rinsed with a mouth-wash, and the teeth cleaned with a soft toothbrush and a dentifrice. Periodical medical and dental examination can achieve a great deal, especially by emphasis on the proper hygiene of the mouth. Cavities in carious teeth are filled, sharp angles smoothed, and stumps and teeth irremediably decayed extracted. In the felt-hat trade the workshops must be well managed and spotlessly clean. Efficient exhaust-ventilation must be applied to remove the particles of fur and all vapours of mercury compounds at the source of origin. The failure of chemists to find an efficient substitute for mercuric nitrate in the felting of fur remains a blot upon modern industrial practice, for although the number of cases of poisoning in Great Britain is now negligible there are many elsewhere. Soviet Russia has had the courage to use potash in place of mercury, but this produces felt of inferior quality. A workman affected by mercurial tremor must give up his work, and abstain from alcohol. Stomatitis should be treated by the use of the toothbrush, mouth washes and dental extractions when necessary. In cases of medicinal poisoning saline aperients should be given daily to promote the free elimination of mercury by the colon.

3. POISONING BY MERCURY FULMINATE

Mercury fulminate is handled in explosives factories where detonators and percussion caps are made. In those processes where the fine dust of this substance falls upon the skin dermatitis follows. The susceptibility of some individuals is such that they cannot stand the dust for a day, whereas others only suffer in warm weather. As a rule the cases of "fulminate itch," as they are called in the trade, are slight. The face, eyelids, neck and fore-arms are attacked by erythema, accompanied by itching, swelling and oedema. Papules break out on the inflamed areas, and may become vesicles, bullae and pustules. A pustular folliculitis commonly develops on the hairy parts of the skin. If the fulminate lodges in a crack or abrasion of the skin it may act as a corrosive, causing small painful necrotic lesions on the hands which last about a fortnight. The operatives call them "powder holes." Recovery

takes place in from 1 to 2 weeks and is accompanied by desquamation. Inflammation of the conjunctivæ and mucous membranes of the nose and larynx may occur.

In the manufacture of mercury fulminate meticulous attention should be paid to detail in all matters of cleanliness in the entire plant. Where fumes are given off as the result of small explosions they must be removed by means of mechanical ventilation. All persons employed should be provided with well-fitting overalls, caps, indiarubber gloves, and if necessary respirators. Washing accommodation must be available close to the workroom, and a separate towel provided for each worker. The hands and arms are washed before meals and before leaving work in a 10 per cent. aqueous solution of sodium thiosulphate. A lanolin ointment is rubbed into the skin after washing. For the conjunctivitis a 2 per cent. solution of sodium thiosulphate as an eyewash has been beneficial.

4. POISONING BY ORGANIC MERCURY COMPOUNDS

Fungicidal dusts containing organic mercury compounds are used extensively in agriculture to prevent certain smut diseases of cereals. For some years mercurial derivatives of the phenyl and tolyl series have been manufactured without any mishap worse than an occasional burn on the skin. Poisoning by inhalation of methyl mercury compounds leads to involvement of the nervous system in a unique way, salivation, stomatitis and erethism being absent. There is severe generalised ataxia, dysarthria and a gross constriction of the fields of vision, memory and intelligence being unaffected. In severe cases the patient remains crippled, and unable to stand or to speak intelligibly. The condition has been reproduced experimentally. Rats and monkeys were exposed to the vapour of methyl mercury iodide and they became grossly ataxic. Histological studies showed myelin degeneration in the peripheral nerves, posterior roots and dorsal columns.

In the manufacture of organic mercury compounds elaborate precautions must be taken to prevent contact with the skin or inhalation. The use of gloves and respirators is not enough. The whole process of manufacture, including the final packing of the dusts, must be carried out mechanically in closed apparatus. The farmer should be protected both by warnings that mercurial dressings are poisonous and by schemes whereby he can obtain from the seed merchant seed already dressed. The seed merchant must dress the seed in a completely closed apparatus. The ataxia and dysarthria of methyl mercury poisoning must be treated by re-educative movements, persuading the patient to walk on chalked lines. An expert in charge of a speech clinic with great patience and the use of a mirror should teach the workman to speak. With great perseverance in some cases he may be taught to use knife and fork, a pencil and even a typewriter.

MANGANESE POISONING

Ætiology.—Manganese is used in the manufacture of dry batteries and in the pottery, soap and colour industries. Cases of poisoning have followed upon the inhalation of excessive amounts of dust in the grinding, sieving

and packing of manganese ores, and in the manufacture of manganese steel in which the metal is first fused in the electric furnace.

Pathology.—Susceptible individuals are few. There is a similarity between this form of poisoning and progressive lenticular degeneration, except that in manganese poisoning the condition remains stationary or improves when exposure to manganese dust ceases. Histological studies on necropsy material have shown degenerative lesions of the nerve cells, particularly in the globus pallidus, the lenticular nucleus and the caudate nucleus. The fact that histological lesions have been found in the liver makes still closer the connection between poisoning by manganese and progressive lenticular degeneration. The condition has been reproduced experimentally in monkeys by administering manganese chloride by intraperitoneal injection. The animals developed choreic movements, passed into a state of rigidity, and finally developed tremor resembling paralysis agitans. Gross morbid changes were found in the lenticular nucleus and liver. The experiments afford an explanation of the symptoms in most of the cases described. The extrapyramidal motor system is clearly picked out by the poison, hence the rigidity, difficult gait, retropulsion, propulsion, mask-like facies, sleepiness, tremor, and uncontrollable laughter.

Symptoms.—The symptoms include languor and sleepiness, low monotonous voice, mask-like facies, involuntary movements varying in degree from a fine tremor of the hands to gross rhythmical movements of the arms, legs, trunk and head, cramps in the calves, retropulsion and propulsion, unsteady gait, and occasionally uncontrollable laughter or crying. There is no disability except in the nervous system.

Prognosis.—Although men seriously poisoned are life-long cripples, the condition is not lethal.

Treatment.—Manganese poisoning can be prevented by wearing respirators wherever dusts or vapours are encountered. Personal hygiene is important, and the worker must wear protective clothing and gloves, since the occurrence of skin absorption is established. Local exhaust ventilation should be applied, both at the furnaces to remove fumes and at the packing and sieving apparatus to remove dust. These measures are attended with good results, for it has been found that when they were applied in one particular factory they removed all risk of poisoning encountered by the workers over a period of 6 years.

CARBON MONOXIDE POISONING

Carbon Monoxide, or Carbonic Oxide (CO), is a very poisonous gas. If present in the air breathed in an amount equal to 0.2 per cent. it is capable of destroying life; while an atmosphere containing 0.05 per cent. of carbon monoxide gives rise to definite symptoms of poisoning.

Ætiology and Pathology.—When carbon is burnt in a limited supply of oxygen, carbon monoxide is produced in varying amount. *Domestic poisoning*: Charcoal fires and braziers give rise to considerable amounts of CO. Certain types of water heaters and slow combustion stoves are common sources of production of the gas, which may give rise to poisoning if the ventilating flues are inadequate. In lime kilns there is evolution of CO₂ and CO. The

exhaust fumes from motor-cars and petrol-burning engines contain approximately 6 per cent. of carbon monoxide. The commonest source of carbon monoxide poisoning is from coal gas which is used for illuminating or heating purposes. Coal gas contains normally a percentage of from 4 to 10 per cent. carbon monoxide, and it often approximates to the latter figure. It is a common cause of death either from accidental leakage of pipes or from purposive exposure due to turned-on taps. Carbon monoxide occurs in the smoke and fumes from fires with inadequate chimney ventilation. It is important to remember that the products of combustion of gas stoves and gas fires contain an appreciable amount of carbon monoxide. The flues from these are often quite inadequate completely to carry away the products of combustion, in which case the gas stoves and gas fires, when used, give rise to the addition of carbon monoxide to the air of dwellings and so are a source of ill-health or chronic CO poisoning. *Industrial poisoning*: This occurs from the fumes from blast furnaces, in iron smelting, and in blasting operations in mines. In coal mines the explosions from coal dust, or inflammable gases, lead to the production of carbon monoxide (after-damp). *Water gas* is prepared by passing steam over red-hot coke, and contains upwards of 30 per cent. CO. It is used for heating purposes, and is sometimes added to coal gas before its distribution. It is very poisonous and, owing to its slight smell, is very dangerous unless mixed with odorous gases. *Producer gas* is prepared by passing a mixture of steam and air over red-hot coke in retorts. It is used for heating the coal retorts for the preparation of coal gas. Producer gas is a mixture of carbon monoxide, hydrogen and nitrogen, and is similar in composition and properties to water gas, and may contain as much as 30 per cent. of carbon monoxide. Industrial dangers also arise from leakages in the plant and from the process of charging the producer-gas retorts.

Action of carbon monoxide.—Carbon monoxide has 220 times the affinity for hæmoglobin that oxygen has. If respired, it will, therefore, more or less completely displace the oxygen from its combination with the hæmoglobin of the red cells. This prevents oxygen being carried in requisite amount by the red cells to the tissues of the body, which thus become deprived of the oxygen necessary for their vital functions. The extent to which the hæmoglobin is saturated with carbon monoxide depends upon the percentage of the latter in the air breathed. When the hæmoglobin becomes one-third saturated with carbon monoxide, definite symptoms of poisoning occur, and when the saturation exceeds 50 per cent. there is grave danger of a fatal issue. It is important to note that carbon monoxide is a tissue poison. It does not act simply as an oxygen depriver to the tissues, but undoubtedly has in addition a narcotic action upon them. This is best illustrated by considering the serious symptoms of narcosis (muscular paralysis and loss of consciousness) which occur in a person in whom 50 per cent. saturation of the hæmoglobin with carbon monoxide exists. These symptoms far exceed in gravity those of a person possessing only 50 per cent. of hæmoglobin as the result of anæmia from disease or hæmorrhage. Carbon monoxide acts as a tissue poison especially to the nervous system, but there is evidence to show that it acts on all the tissues of the body, notably the cardiac muscle, and may cause degenerative changes in them.

Post-mortem appearances.—The external appearances are characteristic,

the cheeks and lips and post-mortem stains appearing cherry-pink in colour. On opening the body, the blood, muscles and internal organs have a characteristic cherry-pink colour. The lungs may show areas of consolidation due to broncho-pneumonia. Small hæmorrhages may be visible, and œdema is common. The brain shows congestion and œdema, and small punctiform hæmorrhages may be found in the cortex and basal ganglia. The heart may show degeneration of the cardiac muscle and punctiform hæmorrhages beneath the pericardium. In some cases of carbon monoxide poisoning putrefaction is much delayed.

Symptoms.—The onset of carbon monoxide poisoning is usually very insidious, since the gas is odourless and any smell of an atmosphere containing it is due to the presence of other gases or vapours having a characteristic odour. Also the gas may be respired freely without any irritation to the air passages. Premonitory symptoms are giddiness, ataxic gait, a swimming sensation, headache or a sensation of heaviness or constriction in the head, noises in the ears, and a feeling of oppression in the chest. Sometimes nausea and vomiting occur. The onset is, however, often sudden, and this is likely to be so when the percentage of carbon monoxide is relatively high. In these cases, the first symptoms may be sudden collapse, with loss of consciousness, and this is associated with complete loss of power of the muscular system. In subacute cases the symptoms may resemble those of acute alcoholic poisoning. An analysis of the blood would at once reveal the exact diagnosis.

Cardio-vascular symptoms, such as violent beating of the heart and throbbing of the blood vessels, occur. The blood pressure rises at first, and the pulse is full and may not be increased in frequency. Muscular weakness and drowsiness quickly supervene in severe cases, and the patient falls unconscious. In the condition of coma the blood pressure falls and the pulse becomes rapid and small. The conjunctivæ become hyperæmic and the eyes have a staring appearance, the pupils being partially dilated, and do not react to light. The complexion has a cherry-red appearance. Froth may be present on the lips. The breathing is stertorous. The temperature is usually subnormal in the early stages of coma, but is sometimes raised above the normal in the later stages. There is relaxation of the sphincters in severe cases. Broncho-pneumonia may develop if the coma is prolonged for more than a few hours. When the state of coma lasts only for an hour or two, the recovery may be rapid. It is very important to remember that though the muscular power recovers quickly, the tissues of the body have been submitted to a serious acute toxæmia. In all cases where coma has occurred, careful after-treatment is essential, since thereby the occurrence of after-effects such as weakness or paralysis, or mental disorder, may be avoided.

Diagnosis.—In all cases, at the earliest opportunity, a specimen of blood should be obtained for analysis. About 10 c.c. are removed from a convenient vein of the arm, and placed in a small test-tube so as almost to fill it, and a cork inserted. This can then be sent to the laboratory for analysis. It should not be shaken or exposed to the air. The carbon monoxide present in the blood is most conveniently estimated by means of Hartridge's reversion spectroscope. The percentage of carbon monoxide present is of value not only for diagnosis but for prognosis.

It may be remarked that a record of the blood analysis in cases of carbon monoxide poisoning would be of great interest and value for research purposes.

Treatment.—Elimination of the carbon monoxide is best effected by the ventilation of the lungs with pure air and oxygen.

Immediate removal of the patient to an uncontaminated atmosphere is the first step. Onlookers should not be allowed near the patient. If removed to a room, the windows and doors should be widely open and a free current of air encouraged. Complete rest is absolutely necessary, and attempts to keep the patient on the move should be forbidden. The patient should be lying flat, and all constricting clothing round the neck and chest should be loosened or removed. Care should be taken that the air passages are free, and any froth or saliva wiped away from the mouth or nose. If necessary, the tongue should be pulled forwards with tongue forceps. In some cases, especially if convulsions have occurred, a gag may be required to keep the mouth open. Warmth of the body is important, and blankets and hot-water bottles should be used.

Artificial respiration is of great value, as this enables oxygen to reach the alveoli of the lung. The method most suitable is Sylvester's, for this permits of free access of fresh air to the air passages and is more convenient for the administration of oxygen. The upper extremities are moved upwards to a fully extended position above the head and kept there for two seconds, they are then lowered to the sides of the chest and firmly pressed against the ribs for about two seconds, the double movements being repeated about fifteen times per minute. Oxygen and 5 per cent. carbon dioxide should be administered without delay. For its efficient administration a cylinder, with a suitable regulating valve tap, and a B.L.B. mask are required. If no cylinder containing the mixture be available a sparklet bulb containing CO_2 may be used in conjunction with an oxygen cylinder. A special metal perforator with tube attached is available for the purpose of perforating the sparklet and admitting the carbon dioxide at a desired rate by means of a rubber tube. The rubber tube is placed under the oxygen mouthpiece, so that the mixture of oxygen and carbon dioxide can be conveniently administered. This method of administration is easily and conveniently effected and is entirely free from any risk. When the respiration of the patient has become normal, pure oxygen should be administered for about 3 hours, with short intervals for feeding. This will be of value in getting rid of the carbon monoxide from the blood of the patient.

Atropine sulphate, gr. $\frac{1}{100}$, may be given hypodermically, and repeated, if required. In severe cases it may be necessary to treat collapse by means of subcutaneous normal saline (1 pint), or possibly blood transfusion.

After-Treatment.—In mild cases, where coma only lasts a short time, it is important that the patient should be kept completely at rest in bed and under medical supervision for a few days. In severe cases, where coma has been prolonged for several hours, complete rest in bed under medical supervision for 2 or 3 weeks or more will be required, since otherwise there is a danger of after-complications. A certain proportion of cases that have been severely poisoned develop confusional insanity. Prognosis for life is then good, but the mental prognosis is poor.

POISONING BY COAL-TAR DERIVATIVES

The coal-tar derivatives are so numerous and complex that it is difficult for the toxicologist to keep pace with the chemists who produce them. The following compounds will be discussed: benzene, nitrobenzene, dinitrobenzene, phenylenediamine, trinitrotoluene, dinitrophenol and aniline. It is sometimes possible to predict from the chemical composition of the simpler members of the group what their physiological action is likely to be. Addition of a nitro- or nitroso-group usually produces a more toxic compound, but it does not follow that toxicity will continue to increase as more nitro-groups are added. Thus, 1-2-4 dinitrophenol is toxic, whereas trinitrophenol is practically harmless. The position of the substituent groups in the benzene ring has a great effect on the toxic action. Thus, the toxic properties of 1-2-4 dinitrophenol are not shared by any of the other isomers. When a nitro-compound is reduced to an amine, as when nitrobenzene is reduced to aniline or nitrotoluene to a toluidine, the toxic characteristics remain much the same, but the intensity of the action is lessened. Sulphonation renders a compound non-toxic; as soon as aniline is sulphonated it ceases to give trouble. The entrance of chlorine into an aromatic compound does not increase the toxicity, as it does in the case of an aliphatic compound. In fact, chlorobenzene is less toxic than benzene.

1. BENZENE

Coal-tar benzene or benzole is obtained as a by-product from the distillation of tar in the manufacture of coal gas. It is the most interesting of the industrial solvents, and with the exception of tetrachlorethane the most dangerous. It must not be confused with benzine, which is unfortunately pronounced in the same way. Benzine is derived from the distillation of petroleum and is non-toxic. Coal-tar benzene has two fields of application in industry: (1) where it is handled in large quantities in closed mechanical systems, as in the distillation of coal-tar, the blending of motor fuel and in chemical industry; and (2) where it is used as a solvent, as in the rubber industry, artificial leather manufacture, the dyeing and cleaning industry, the manufacture of paints, varnishes, celluloid, artificial manure and glue.

Acute benzene poisoning usually occurs as the result of the breaking of distilling apparatus, or in the cleaning of tanks. In slight cases there is giddiness, and a stage of excitement; in severe cases these symptoms may be followed by convulsions, coma and death. Benzene sinks into the metal of tanks. It is therefore necessary to forbid men to enter such tanks until they have been washed clean and exposed to the open air for many days. Even then a workman lowered into such a tank must be equipped with body belt, life-line and breathing apparatus communicating with a hose to the exterior. In the stage of excitement the victim may shriek, sing madly and fight with the rescuer, who, on account of his greater exertions, runs more risk than the rescued.

Chronic benzene poisoning has always been very rare in Great Britain. Speaking for the whole world, however, it was at one time the most important industrial poison after lead. Benzene poisoning may begin with giddiness,

nausea, anorexia, weakness and nervousness. These symptoms are followed by progressive anæmia, with hæmorrhagic manifestations, such as bleeding gums, epistaxis, menorrhagia, purpura and visceral and retinal hæmorrhages. Ulcers or gangrenous patches on the lips, fauces and pharynx are common. Although poisoning may occur only after many years' exposure there have been fatalities after a few weeks' exposure. The victims of industrial poisoning often constitute a small minority of the workers; a single susceptible individual may contract fatal poisoning in an environment which does not give rise even to mild poisoning in others. The factors responsible for the great variations in susceptibility are largely unknown, but in general, women, especially young women, are more susceptible than men. Changes in the blood may begin from 2 days to 1 month after the first exposure, according to the amount absorbed, and they may progress or even develop after exposure has ceased. Acclimatisation to the vapour of benzene does not seem to occur, and it is doubtful whether any concentration greater than zero is safe over a long period of time.

The bone marrow is attacked, and it may be aplastic, normal, hyperplastic or leukæmic, the corresponding changes being reflected in the peripheral blood. In the early stages of poisoning there may be little or no evidence of damage to the red cells but only purpura with leukopenia and granulopenia. The total leucocyte count may fall to a very low level; in fact, the white cells may almost disappear. A count of one thousand per c.mm. is common. In some cases the granular leucocytes fall as low as 10 per cent. The bleeding time may be increased to half an hour, with a corresponding drop in the platelets. The red cell count may fall as low as three-quarters of a million per c.mm. Splenomegaly may appear in protracted cases of poisoning. Myeloid leukæmia, confirmed by post-mortem examination, has been found in several cases. Necropsy usually shows aplasia of the bone marrow. Hæmorrhages may be found in the skin, pericardium, pleura, alimentary tract, meninges, bladder and uterus. Gangrenous stomatitis and even necrosis of the gastric mucosa have been recorded. Benzene cannot be discovered in the body after death.

Benzene is so toxic that its substitution wherever possible by other solvents which are harmless is in preventive treatment the method of first choice. In all processes involving the presence of benzene the value of frequent periodical medical examination, including examination of the blood, has been proved by experience. The more complete and effective the prevention of the escape of vapours into the workrooms and the more efficient the daily supervision of the ventilating apparatus, the less is the necessity for periodical medical examination.

In acute benzene poisoning the usual methods of resuscitation are used: rest, warmth, artificial respiration, administration of oxygen and carbon dioxide mixture, and injection of coramine as a respiratory stimulant. The patient should be prevented from returning to work too early.

Cases of chronic benzene poisoning must be treated by repeated blood transfusions and it must be remembered that the toxic influence may persist even after removal from exposure. The results of treatment are so poor as to convince all who have studied the subject that the use of benzene in industry must be ruthlessly suppressed, except where the process used is entirely enclosed. Fortunately in Great Britain it has been possible to do this.

2. NITROBENZENE

Nitrobenzene (mono-nitrobenzene: oil of mirbane; artificial oil of bitter almonds) is used in the manufacture of aniline, in perfumery and as a flavouring agent, being the chief substitute for oil of bitter almonds. It is sometimes taken as an abortifacient, and on several occasions 15-25 drops have proved fatal, especially if the poison is taken with alcohol. The stomach should be washed out repeatedly with water until the returned fluid no longer smells of nitrobenzene. Purgatives should be given. In factories death has taken place from absorption through the skin, where the oil has been spilled on the clothing. The victim of such an accident should be stripped promptly of his clothes, sponged with weak acetic acid or vinegar, and provided with a shower bath and clean clothes. The symptoms vary according to the acuteness of the poisoning. Pallor appears, quickly followed by lividity. Unconsciousness occurs with great rapidity, perhaps in 20 minutes. The patient is generally deeply cyanosed, and the blood is dark and viscid, and will sooner or later show the spectrum of methæmoglobin. Death occurs in coma, or recovery takes place after a variable period of unconsciousness. However, nausea and vomiting may begin again after a few days, and toxic jaundice appear. The blood picture is that of anæmia with granular degeneration of the red cells (stippling), and sometimes the presence of nucleated red cells. In severe anæmia a blood transfusion may be considered.

3. DINITROBENZENE

Dinitrobenzene is used in the manufacture of dyes, and is itself an important explosive. It is a solid, and in consequence poisoning develops less rapidly and is less severe than in the case of mono-nitrobenzene. Poisoning occurs amongst men who either shovel or melt dinitrobenzene. In a mild case there is a sense of pressure in the head, which increases to a violent throbbing headache, giddiness and dyspnoea. In severe cases the face is deeply cyanosed; the lips, tongue and ears are deeply purple; and there are nausea, sometimes vomiting, abdominal pain, a staggering gait and extreme weakness. An attack rarely occurs during work; the man is usually overcome some hours after he has left the plant. Cyanosis occurs, and is accompanied by anæmia with marked stippling of the red cells. Methæmoglobin, hæmatoporphyrin, hæmoglobin, and even albumin have been found in the urine. The smoky colour of the urine may be noticed by the men themselves soon after their first contact with nitrobenzene or aniline. Only very rarely does toxic jaundice occur. It is well known in industry that cases of poisoning are more frequent in hot weather than during the colder seasons of the year. Lack of care and unclean habits are predisposing causes. Those who do not change their working clothes on returning home may sit before the fire and absorb the poison from the evaporation of crystals or from the material in solution on their clothing. Absorption from the alimentary canal is more rapid if the stomach is empty, and it is therefore desirable that men should take a meal before they work. Alcohol undoubtedly favours absorption, and several instances are on record in which poisoning has supervened after indulgence in ordinary amounts.

4. PHENYLENEDIAMINE

Phenylenediamine is used for two similar purposes; for dyeing hair black and as a dye for furs. It is well known that it may cause dermatitis and sometimes asthma in susceptible persons. Its systemic effects are much rarer and have received less attention. Hairdressers handling the dye have suffered from attacks of weakness and vomiting, with intense violet cyanosis of the lips and face. In unusually susceptible individuals toxic jaundice has occurred, followed by death from hepatic insufficiency after about 6 months. At necropsy the liver is small and shows the changes of subacute atrophy with regeneration nodules. Persons handling the dye should wear rubber gloves. Avoidance of exposure removes the cyanosis completely.

5. TRINITROTOLUENE

Trinitrotoluene is handled mainly in the filling of shells. The first symptoms of poisoning are drowsiness, headache, nausea, loss of appetite, epigastric pain, vomiting and giddiness. There is some cyanosis of the lips, followed by dyspnoea with marked drowsiness and staggering gait. Dermatitis in the form of a diffuse erythema sometimes occurs on the dorsal surfaces of the wrists, and on the face and neck. The symptoms come on gradually after several days' or weeks' work, or they appear on a hot day after a few hours' work and cause collapse. If cyanosis occurs in one in ten of the workers, toxic jaundice probably affects one in five hundred. The greatest incidence of jaundice is in the third month of employment. Premonitory symptoms, such as drowsiness, giddiness, depression, and dark urine are sometimes present, but the onset is often quite sudden. Sometimes a latent interval occurs between removal from exposure and the onset of jaundice. The prognosis is always uncertain, but grave symptoms of hepatic insufficiency sometimes appear rapidly. The mortality is 25 per cent. The morbid appearances are those of yellow and red necrosis of the liver, with great reduction in its size and weight. The necrosis of the liver cells is associated with infiltration and subsequent fibrosis resembling ordinary portal cirrhosis. Aplastic anæmia sometimes occurs among trinitrotoluene workers, but its incidence is very small. The latency of the blood changes is even longer than the latency of the jaundice, for it is found that anæmia can develop as long as 9 months after exposure to trinitrotoluene has ceased. The anæmia is usually, if not always, fatal. At necropsy fatty marrow is found throughout all bones. There is an excess of iron pigment in the liver, and multiple hæmorrhages are found in the tissues. The skin is the main channel of absorption. Experience in industry goes to show that when a poison is absorbed by this route the application of preventive measures is most difficult; trinitrotoluene is no exception. By the end of the War of 1914-1918 the risk of poisoning had been greatly diminished, not by any single precaution but by the combination of several, of which alternation of employment, periodical medical examination, ventilation and clean working conditions were the chief. Success was not achieved until mechanical means were substituted for the hand filling of shells, combined with measures of cleanliness which were so precise as to prevent the contamination of the outside of the shell by trinitrotoluene.

6. DINITROPHENOL

It is the 1-2-4 isomer of dinitrophenol which has toxic properties. These were revealed in the War of 1914-1918, especially in French shell-filling factories. The illness begins with lassitude, and the worker may notice yellow patches on the covered parts of the skin due to excretion in the sweat of dinitrophenol. Tremor, excitement and intense thirst follow, and the face may be slightly cyanosed. In severe cases orthopnoea, hyperpyrexia and convulsions set in, and death occurs in a condition resembling uræmia. The urine is of an orange yellow colour, and gives a diazo reaction, which serves both quantitatively and qualitatively to determine the amount of the poison absorbed, and so to give a clear indication as to when suspension and transference to other work are necessary. At necropsy no pathognomonic feature is found; there is no atrophy of the liver. The workmen must be provided with a complete set of underclothing and overalls into which they change from their working clothes, a separate cubicle being provided for each man. Well designed exhaust ventilation must be applied locally to take away the fumes in the melting of the compound and also in the filling of shells. Any dust that collects around the margin of the shell must be removed by a vacuum cleaner.

In 1933 dinitrophenol became widely used in the treatment of obesity, especially in the U.S.A. A dose of 3 mg. per kg. of body weight will cause a rise in basal metabolic rate and loss of weight, unattended by tachycardia. Toxic symptoms were soon reported, including urticaria, exfoliative dermatitis, jaundice, peripheral neuritis, loss of power to discriminate between sweet and salt tastes, fullness in the ears, deafness, fall in blood pressure, albuminuria, neutropenia, and fatal agranulocytosis. After dinitrophenol had been employed for 4 years cataract was found to be a late complication of the use of the drug. It appears from 3 months to 18 months after the first dose is taken, the change is bilateral, and the lens fibres alter so quickly that the cataract swiftly progresses to total blindness. This final disastrous effect of dinitrophenol brought to a close the unfortunate popularity of this drug.

7. ANILINE

Aniline is a colourless oily liquid which darkens on exposure to light or air. It is handled in the manufacture of dyes, in the dyeing and cloth-pressing industries, in the extraction of resin and in the rubber industry. Aniline poisoning arises usually from inhalation, but absorption through the skin and less frequently inhalation of dusts of aniline compounds may cause it. Care must be taken to change the clothes at once whenever they are splashed with aniline. Men must avoid entering chambers filled with its vapour. The symptoms of aniline poisoning are similar in all respects to those of nitrobenzene poisoning. The convenient term *anilism* may be used to cover the symptoms produced by most of the nitro- and amino-derivatives of benzene.

In *acute aniline poisoning* there is headache, weakness, difficulty in breathing, cyanosis, loss of power in the limbs and giddiness. In severe cases the cyanosis is more intense and prostration occurs with a cold moist

skin, small pulse, air hunger and even death in coma. When recovery occurs it is often gradual and may be accompanied by increased frequency of micturition. In *chronic poisoning* the workers show slight cyanosis, secondary anæmia, and sometimes sleeplessness, headache, giddiness and abdominal discomfort. In hot weather practically all the men exposed to aniline and similar compounds in a dye works show cyanosis.

The manufacture of nitrobenzene, and the reduction of nitrobenzene and nitrotoluene to aniline and toluidine must take place in closed vessels. Even so, escape of small quantities of aniline into the atmosphere is very difficult to prevent unless ample ventilation is provided. Therefore in addition to the technical regulations there must be insistence on cleanliness of the workrooms, personal cleanliness on the part of the workers and provision of baths and changes of clothing. Contact with aniline and nitrobenzene, especially on the skin, and also the spilling and splashing of these fluids must be carefully avoided. All workers must be strictly instructed as to the symptoms of nitrobenzene and aniline poisoning, and the right steps to take if poisoned. Regular medical inspection of workmen is desirable.

Workers, and especially those newly employed, must be under supervision in order that assistance may be rendered them on the first signs of poisoning. Medical assistance should be within easy reach. Systematic instruction should be given in first-aid methods, and in the use of apparatus for oxygen and carbon dioxide inhalation. The possibility of skin absorption must always be borne in mind. A victim whose skin or clothing has been splashed with aniline may turn blue in the face and begin to stagger. Someone may take him out to the fresh air or administer oxygen, when what he needs most is to have his clothes stripped off and be given a bath. Workers entering stills and similar chambers should always be equipped with breathing apparatus and a supply of oxygen. Other aids, such as safety belts which are held by helpers, involve certain risks, especially as the rescuer is easily induced to spring to the assistance of his unfortunate mate without the necessary breathing equipment. The frequency of such accidents calls urgently for the use of breathing apparatus.

POISONING BY CHLORINATED HYDROCARBONS

The rapid growth of the moulded plastics and cellulose lacquer industries has led to the extensive use of many new solvents, most of which were little more than chemical curiosities before about 1925. Amongst these are the chlorinated hydrocarbons which have flooded the market largely because the alkali industry requires an outlet for its by-product chlorine. The various members of the group are useful as refrigerants, as degreasers of metals, fire-extinguishers, cleansers of textiles, solvents for rubber and thinners of cellulose lacquers. They are non-inflammable, non-combustible, and non-explosive, but they are far from harmless in their effects on the human body. The action of carbon tetrachloride has been extensively studied because of its use in hookworm therapy. Tetrachlorethane dramatically attracted attention in England in 1914. A mass poisoning from leaking refrigerators in Chicago in 1929 led to an increase in knowledge of the action

416 DISEASES DUE TO PHYSICAL & CHEMICAL AGENTS

of methyl chloride. Trichlorethylene has been studied because of its extensive use in dry cleaning. It led to trouble in German industry in 1931. Chlorinated naphthalenes caused no serious harm until 1936.

1. METHYL CHLORIDE

Men working in chemical plants or employed upon making, installing or repairing refrigerators may be exposed to methyl chloride. Symptoms of poisoning include giddiness, weakness of extremities, nausea, vomiting, restlessness, followed by somnolence, and then by dimness of vision, which may not clear up until 14 days after removal from exposure. Later there is some rise of temperature, pulse, and respiratory rate, usually with oliguria and occasionally with suppression lasting up to 48 hours. Evidence of acute nephritis is found in about half the cases. Anaemia may be found, the red cells dropping as low as 3 million per c.mm., and the haemoglobin as low as 50 per cent. The death-rate is as high as 35 per cent.

2. CARBON TETRACHLORIDE

Carbon tetrachloride is used in industry as a solvent for fats and rubber, for dry cleaning, for cleaning oil from machinery, and under the name pyrene as a fire extinguisher. Acute and sometimes fatal poisoning has occurred from the anaesthetic effects of carbon tetrachloride used as a dry shampoo for the hair. Men exposed to the vapour sprayed from pyrene fire extinguishers in confined spaces have suffered from oliguria and jaundice. In animal experiments carbon tetrachloride has been shown to cause necrosis of the liver. In man it may attack both liver and kidneys, but in most clinical histories so far published the symptoms of renal injury overshadow those of hepatic injury. The early stages of the illness are characterised by persistent headache, nausea, vomiting, diarrhoea and tenderness over the liver. Such symptoms are often followed by oliguria, suppression of urine and uræmia. The blood urea may rise to 300 mg. per 100 c.c. and the patient, though practically moribund, may suddenly develop polyuria and recover even after almost complete anuria lasting 10 days. When the liver is attacked recovery may follow an attack of jaundice lasting as long as 2 months. In the treatment of cases rendered unconscious by acute poisoning, it is important that the patient should not be placed upon the floor of the room where the accident occurred, for the vapour is five times denser than air and therefore accumulates on the floor. Chronic poisoning should be treated by glucose drinks, together with large doses of calcium lactate up to 15 grammes a day. If necessary calcium gluconate may be given by intramuscular injection.

3. TETRACHLOROETHANE

Tetrachlorethane is the most dangerous of all the chlorinated hydrocarbons, being nine times as toxic as carbon tetrachloride. It is a very good solvent for cellulose acetate, which, being non-inflammable, is used for purposes for which cellulose nitrate (celluloid) is not adapted. Cellulose acetate was the chief constituent of the dope used as a waterproof coating for the wings of aeroplanes in the War of 1914-1918, and it is now used to make non-inflammable cinema film. The symptoms of poisoning are general

malaise, loss of appetite, nausea, headache and constipation. After several days or even weeks, jaundice develops and vomiting is then likely to become more marked. In fatal cases necrosis of the liver is found in the form of acute red and yellow atrophy. In one case the liver weighed only 19 oz. The blood changes in mild poisoning consist of an increase of large mononuclear cells up to 40 per cent., with a slight elevation of the white count. Blood counts have been taken in order to detect early poisoning. Elaborate exhaust ventilation in factories and workshops fails to prevent toxic jaundice. It is therefore necessary to use a harmless solvent, such as amyl acetate in place of tetrachlorethane.

4. TRICHLORETHYLENE

Trichlorethylene is a non-inflammable solvent employed extensively in dry cleaning. It has assumed an important place in the list of fat and rubber solvents, displacing to some extent carbon tetrachloride. Trichlorethylene has a powerful narcotic effect. The workman affected is usually found unconscious on the floor, and if there has been prolonged exposure to a large dose the effects may be fatal. Chronic exposure has been held responsible for paralysis of the sensory fibres of the fifth nerve, and also for retrobulbar neuritis followed by optic atrophy. An indirect form of injury to the eye sometimes occurs when a foreign body lodges in the cornea and produces ulceration. The workman is not aware of the presence of the irritant substance, because the cornea has been rendered insensitive. Apparently trichlorethylene is not so likely to attack the liver as tetrachlorethane. Toxic jaundice and albuminuria have only rarely been recorded. Dry-cleaning establishments employing trichlorethylene should be provided with efficient exhaust ventilation. When solutions containing trichlorethylene are applied to the interior of closed vats the men should work in pairs, relieving each other frequently. The man in the enclosed space should be provided with a lifebelt and also with an apparatus through which he can breathe air from outside.

5. CHLORINATED NAPHTHALENE

When naphthalene is chlorinated a wax-like substance is produced. It is used as an insulating coat on wires or on metal bars to circumscribe the action of plating processes. It may produce acne, starting on the face and around the angles of the jaws and malar prominences, and spreading on to the sides of the face, neck, shoulders and forearms. The skin lesions in a typical case are comedones, papules, pustules, and in severe cases small cysts. Since 1936 several cases of jaundice have occurred in workers handling chlorinated naphthalenes. In one fatal case necropsy showed acute red and yellow necrosis of the liver, which weighed 650 gm., the normal being 1,500 gm. By attention to ventilation, protective clothing and medical supervision of workers, the chlorinated naphthalenes can be handled in industry with safety.

DONALD HUNTER.

ACKEE POISONING

Synonym.—Vomiting sickness of Jamaica.

Definition.—A frequently fatal disease, especially affecting children in the West Indies, characterised by vomiting and nervous symptoms due to eating the unripe ackee fruit.

Ætiology.—Ackee fruit grows on the tree *Blighia sapida* (Sapindaceæ) in the West Indies and West Coast of Africa. The mature fruit is harmless, but when eaten in an immature state before the fruit opens, it proves a deadly poison, especially if soup be made from it or other ingredients like rice be boiled in ackee water. The poison is contained in the arilli of the unripe fruit.

Pathology.—Intense fatty changes are found constantly in the liver and to a lesser degree in the kidneys, heart and cortical brain-cells. Hyperæmia of the meninges and other organs occurs, also hæmorrhages in the viscera.

Symptoms.—The patient, who is generally a healthy child, suddenly commences vomiting some two hours after a meal containing unripe ackee fruit and complains of nausea and abdominal discomfort. After three or four hours of sickness a calm interval ensues, followed by nervous symptoms, including cerebral vomiting, twitching of muscles, convulsions and coma.

Prognosis.—Once nervous symptoms supervene the condition is invariably fatal, the average duration being 12 to 14 hours.

Treatment.—Prevention consists in discarding the immature unopen fruit and in not utilising the water in which ackee fruit is boiled as soup. Alcohol precipitates the poison, and the immediate administration of rum or ether and ammonia as advocated by Scott has reduced the mortality in school children from 90 to 27 per cent.

N. HAMILTON FAIRLEY.

FOOD POISONING

Food poisoning occurs when, in mistake for a wholesome food, some article is eaten which is of itself normally poisonous, or rendered poisonous by contamination from outside sources. The former is called Endogenous Food Poisoning, while the latter, which is the ordinary form of food poisoning, is spoken of as Exogenous.

EXOGENOUS FOOD POISONING.—The following are examples :

(1) *Poisonous fungi* are sometimes eaten in mistake for edible mushrooms, and dangerous or even fatal results may follow, owing to the presence in them of poisonous substances. Unfortunately there are no simple tests by which the layman may distinguish the poisonous from the harmless species. Experiments in eating new or unfamiliar varieties should never be undertaken.

(a) *Amanita phalloides*.—This contains the deadly substance, phallin or amanita toxin. The susceptibility of children is greater than that of adults. The ingestion even of part of a plant may result in poisoning and

the mortality rate is high. After a prodromal period of 4 to 24 hours, acute abdominal pain, vomiting and diarrhoea occur. The vomit and stools may contain blood and mucus. Anuria may occur. Short periods of remission may follow, but usually within a day or two jaundice, cyanosis, and coldness of the extremities develop. In fatal cases coma supervenes. When poisoning is less severe, the symptoms abate in about a week and the patient is well within 4 weeks.

(b) *Amanita muscaria*.—This contains muscarine. After a small dose the patient becomes mildly excited, and the fungus is used by Siberian peasants to induce drunkenness. After larger doses the first symptoms appear within 2 to 6 hours. They are salivation, sweating, retching, vomiting and diarrhoea. Giddiness, confusion and hallucinations rapidly follow, and the pupils become contracted and fail to react to light or on accommodation. Amaurosis and diplopia may occur. Although the symptoms are violent the mortality rate is low. In all cases of mild poisoning the prognosis is good.

(2) *Poisonous fish*.—Certain fish, such as those of the species *Tetrodon*, found in Japanese waters, are normally poisonous, and the same applies to mussels when grown under unhealthy conditions. The symptoms caused by these poisonous foods are those of acute gastro-enteritis, with marked nervous disturbance and collapse.

(3) *Poisonous parts of plants* may be eaten in mistake for foods; for example aconite root for horse radish, or deadly nightshade berries for edible fruit.

POTATO POISONING.—Under certain conditions potatoes may contain a dangerous amount of the poisonous alkaloid solanine. This is produced by the growth of certain forms of bacteria in the tubers, which is likely to occur if, owing to improper storage, sprouting of the potatoes has taken place. The symptoms of solanine poisoning are those of acute gastro-enteritis, associated with nervous prostration and collapse, resembling those caused by poisonous fungi.

In some countries certain harmful vegetables are more or less habitually used as foods. [See (4) and (5).]

DONALD HUNTER.

4. LATHYRISM—

Definition.—A disease of limited geographical distribution, characterised by spastic spinal paralysis, and caused by poisoning with peas of a vetch of the genus *Lathyrus*.

Ætiology.—The disease, formerly met with in Italy, has been reported from India, especially North Behar and the United Provinces, Algiers, France, Persia, etc. Three species of *Lathyrus* may be associated with poisoning in man: (1) *Lathyrus sativus*, known in India as Khesari dal; (2) *Lathyrus cicera*, the dwarf chick-pea found in France, Italy and Algeria; and (3) *Lathyrus clymenum*, found in Spain, North Africa and the Levant. It is solely confined to countries where different kinds of chick-pea are used for food, but the causative principle is unknown. Young people are specially liable, and men are more affected than women. It occurs as an epidemic amongst the poorest classes in times of great scarcity, when bread is made from a mixture of pea and wheat flour. It may also be eaten as porridge,

420 DISEASES DUE TO PHYSICAL & CHEMICAL AGENTS

or the peas may be boiled with oil and then consumed. Formerly it was attributed to the grain of *Lathyrus sativus* (Khesari dal), but in India, Howard, Anderson and Simonsen failed to demonstrate any poisonous principle. They succeeded in isolating two toxic alkaloid-like bases, vicine and divicine from *Vicia sativa* (akta), an allied vetch, the seeds of which were a common contaminant of Khesari dal and produced symptoms of lathyrism when fed to ducks.

Pathology.—A chronic sclerosis is found in the spinal cord involving the posterior and lateral columns. Possibly a toxic spasm of the arteries of the cord, followed by thrombosis, is the basis of the condition.

Symptoms.—The onset may be insidious with backache, burning pains and weakness of the legs, or it may be sudden, as when after a hard day's work in the rain the patient wakes up with stiff, weak and trembling legs, which feel heavy to lift. These symptoms increase rapidly, and in ten days walking may be impossible without the aid of a stick. Both legs are usually affected simultaneously, first the calves, then the thighs. Gradually a peculiar gait develops, the patient laboriously progressing by means of a two-handed staff; "the leg bearing the weight of the body is bent at the knee and trembles, while the advancing limb dragged wearily forward and strongly abducted, is planted unsteadily directly in front of its fellow, the toes reaching the ground first." When lying on the back, spasm of the adductors ceases and the thighs can be separated. There is little or no atrophy or loss of muscular tone, the knee-jerks are increased and ankle clonus is marked. Sensation is normal. Incontinence of urine and feces and possibly loss of sexual power follow involvement of the lumbar enlargement, but the upper extremities are rarely implicated.

Diagnosis.—The occurrence of multiple cases simultaneously and the history of eating chick-peas as food confirm the diagnosis.

Prognosis.—This depends on the stage at which the case is diagnosed; if early, great improvement follows treatment, but in later cases when the cord has become permanently damaged spasticity persists.

Treatment.—Varieties of chick-pea must be avoided as human food, and their abolition stamps out the disease. Avoidance of damp and wet ameliorate the symptoms. A generous diet adequate in vitamins should be given. Massage and electricity are indicated.

N. HAMILTON FAIRLEY.

EXOGENOUS FOOD POISONING.—The contamination may be due to bacteria, or to fungi, or to chemical substances.

A. Contamination by Bacteria.

(1) The commonest type of food poisoning is that caused by contamination with *Salmonella* and other organisms. It is described under the heading "Bacterial food poisoning" (see p. 422).

(2) Specific diseases may be caused by the accidental contamination of food with the specific pathogenic organisms. Thus typhoid or paratyphoid fevers may be caused by milk or oysters containing the specific bacilli; scarlet fever or diphtheria by infection of milk with the specific organism; cholera by the contamination of foods or water with cholera germs, amebic

dysentery by contamination with the specific amoebæ or their cysts, and bacillary dysentery by infection of food with its specific bacilli.

A very common cause of these forms of food poisoning is the handling of food by persons known as "carriers," who are apparently healthy but harbour in their bodies the specific germs of a particular disease, their excreta containing large numbers of the pathogenic organism, so that it is an easy matter for the infection of a food-borne disease to be conveyed by the hands of a "carrier" who is engaged in any way in the handling of food; cooks or milkmen frequently spread infection in this manner. The course of the disease is exactly similar to that described under the diseases in question.

(3) Diseases in animals communicable to man may arise from the consumption of food derived from a diseased animal. Thus the flesh of an animal which has died from anthrax may give rise to this disease in man. Tuberculosis of the mammary glands in the cow will cause the presence of tubercle bacilli in milk, the consumption of which may give rise to human tuberculosis. The flesh of animals suffering from actinomycosis may cause this disease in man. Parasitic diseases, such as trichinosis and tapeworm infections, arise from the consumption of the flesh of animals suffering from these infections. These types of food poisoning are fully described under the diseases in question.

(4) Specific organisms may produce in food highly poisonous toxins, the ingestion of which causes acute and perhaps fatal illness. An instance of this is Botulism (see p. 429).

B. Contamination by Fungi.

ERGOTISM.—The grains of cereals attacked by the ergot fungus (*Claviceps purpurea*) are poisonous, and if consumed give rise to a series of symptoms known as ergotism. Two types of this condition are known—(a) *The gangrenous type*. The onset is with numbness beginning in the extremities, and in the course of a few days gangrene appears in the fingers, toes and sometimes the lobes of the ears and tip of the nose. There is agonising pain which penetrates the affected limb like fire—hence the name, centuries old, *St. Anthony's fire*. Later there is complete anæsthesia in the affected part which becomes livid and then black. (b) *The nervous type*. The illness begins with numbness of the hands and feet and twitchings of the muscles of fingers and toes extending to the arms, knees, shoulders, hips and ultimately to the whole body. Severe giddiness, fits, blindness, deafness, delirium and stupidity passing on to dementia are also known. Histological examination shows that the dorsal columns are particularly involved.

C. Contamination by Chemical Substances.

Chemical poisons may accidentally contaminate foods and give rise to the special symptoms of that kind of poisoning. Examples of this are:

Metallic poisoning resulting from contamination of tinned foods by poisonous metals derived from the container. This is a rare form of poisoning, and is only likely to occur when the contents of the tin are liquid, such as fruit juice, liquefied jelly or soups. If the tin is sound, and care is taken in the canning and in the soldering process, so that the solder does not come in contact with the contents of the tin, the risk of poisoning is negligible. Cases of poisoning have occasionally occurred from the solution of lead, derived

from the solder, coming in contact with the contents of the tin. The symptoms of metallic poisoning are described elsewhere.

Arsenical poisoning from the contamination of commercial glucose during its manufacture is described under arsenical poisoning.

Drinking water may be contaminated by lead and give rise to chronic poisoning.

Food preservatives, such as boric acid, formalin, and salicylic acid, if added to foods, may give rise to illness from their toxic effects. The addition of food preservatives to milk is for this reason prohibited by law in this country.

BACTERIAL FOOD POISONING

Synonym.—Ptomaine Poisoning.

This is the form of poisoning caused by the contamination of food with *Salmonella* and other organisms. The resulting symptoms are caused by the bacterial toxins produced in the food by its contamination. There may also be an actual bacterial infection, should the organisms not be killed in the process of cooking. Since bacterial contamination finds a most suitable culture medium in foods rich in protein, this type of food poisoning usually follows the consumption of meat, fish or milk—especially meat.

It was formerly thought that food poisoning was caused by the presence in food of poisonous alkaloidal substances called ptomaines, produced by putrefactive changes. Neurine and mydalcine are examples of such. It is now known that ptomaines are very rarely, if ever, the cause of food poisoning, but that the usual cause is bacterial contamination of food. It is possible that in the consumption of food highly advanced in putrefaction, such as high game, ptomaines may play a part in the causation of toxic symptoms, but cases of this kind are uncommon.

Ætiology.—*Predisposing causes.*—Contaminated food has a much more serious effect on persons suffering from pre-existing gastro-intestinal disease. Thus the presence of colitis or enteritis greatly increases the susceptibility of the patient to bacterial food poisoning, and the resulting symptoms are likely to be more severe than in a person previously healthy. Dysentery or post-dysenteric colitis has a like effect. Starvation or malnutrition increases the susceptibility to bacterial food poisoning, and emptiness of the stomach at the time of taking of contaminated food is likely to lead to the earlier onset and greater severity of the symptoms produced. The above considerations help to explain the remarkable fact that sometimes when several persons partake of the same unwholesome food some may suffer from serious symptoms of food poisoning, while others may have only very slight symptoms, or even be unaffected. Young children are much more susceptible. In hot climates bacterial food contamination is likely to be followed by a very rapid development of bacterial poisons. Dust, flies, dirt and insanitary conditions generally are likely to favour the contamination of food with the bacteria of food poisoning. Careful storage of food in refrigerators where it can be kept free from contamination, is most important.

Meat poisoning may be due to contamination of the flesh during the cutting-up process by the butcher, or the meat may be contaminated either in the process of cooking or afterwards, owing to lack of care in storage.

Sausages.—Many epidemics of poisoning have occurred from infected sausages. This can be readily understood, since the process of mincing, which the meat undergoes, renders it liable to contamination. Moreover, in sausages it is easy for unwholesome meat to be used, with little possibility of detection. The fact that sausages are made with raw or only partly cooked meat, and that they are frequently eaten merely smoked, with little or no cooking, still further adds to the risk.

Tinned meat.—This has been frequently the cause of food poisoning. The meat may be contaminated by *Salmonella* organisms before tinning, and though the process of canning, by the heat applied, may kill the microbes, yet the toxins may not be destroyed, and these will give rise to symptoms of poisoning when the food is eaten. During the War of 1914–1918 tinned meat was consumed in enormous quantities by our troops. Very few cases of food poisoning from tinned meats were recorded, and in those cases where investigations were made the cause of the poisoning was traced to infection of the food after the tins had been opened. Usually the food had been handled by a cook who was a “carrier” of food poisoning organisms. At the present time so much care is taken in the selection of the meat and in the whole process of canning that tinned meat from a reliable source can be regarded as one of the safest foods.

Fish.—Numerous epidemics of food poisoning have been due to eating fish. These have been traced to the contamination of the fish with bacteria of the type already described, and the resulting symptoms have been similar in character. Cooking the fish—boiling or frying—may not entirely destroy the toxins present.

Shellfish.—These are sometimes grown in waters contaminated by sewage containing typhoid and *Salmonella* bacilli. Mussels, oysters, lobsters, crabs, etc., have frequently caused severe attacks of food poisoning, and commonly the shellfish appeared perfectly fresh, with no objectionable taste or smell. Under the Ministry of Agriculture and Fisheries in this country special researches have been successfully carried out on the purification of shellfish for human consumption, particularly in the case of oysters and mussels. These shellfish, if obtained from accredited sources of supply under government supervision, can at the present time be guaranteed as free from pathogenic infection, and regular tests are made to ensure the safety of the shellfish put on the market.

Tinned fish.—This, like tinned meat, may give rise to poisoning from the contamination of the food by bacteria before canning. It is important to remember that tinned fish, even if wholesome at the time the tins are opened, is very liable to bacterial contamination. It should never be kept, but should be eaten on the day of opening.

Vegetables and fruit.—These may, if contaminated by bacteria of the type described, give rise to the disease. Since, however, the bacteria find vegetables an unsuitable medium for growth, outbreaks of food poisoning from vegetables are uncommon.

Milk.—Milk has on several occasions been the cause of outbreaks of food poisoning, and both *Salmonella* organisms and staphylococci have been found present in the affected milk. If milk is infected with the microbes, all that is necessary is a suitable temperature for their growth, and it speedily becomes a dangerous article of food. It is readily understood, therefore, that

these cases are of much commoner occurrence in the warm weather of summer. Carriers of *Salmonella* organisms are a common cause of outbreaks due to milk or cream. Milk and cream may be contaminated with pathogenic organisms, and give rise to epidemics, e.g. typhoid and paratyphoid fever, from polluted water or from carriers handling the milk. In a similar manner outbreaks of tonsillitis and scarlet fever may result from carrier infections.

DONALD HUNTER.

BACTERIOLOGY.—Following work by Savage in this country, and by Jordan in America, bacterial food poisoning came to be regarded as synonymous with infection by food-borne *Salmonella* bacilli. This group of bacilli, like typhoid and dysentery bacilli fail to ferment lactose, but differ by fermenting glucose, mannite and dulseite with the formation of gas.

In the first decade of the century the best-known bacilli of this group were the paratyphoid and enteritidis bacilli, but in 1912 Bainbridge, in the Milroy Lectures, differentiated *Bact. enteritidis aertrycke* from *Bact. paratyphosus* B, and established the fact that *Bact. aertrycke* was a much more important cause of acute epidemic food poisoning than *Bact. paratyphosus* B. By absorption methods of agglutination he showed that the two bacilli were separate entities, although their sugar reactions were identical. *Bact. aertrycke* was subsequently identified with *Bact. typhi-murium*, by which name it is now known. The result of Bainbridge's work was to establish the fact that with few exceptions epidemic food poisoning is caused by *Bact. typhi-murium* or *Bact. enteritidis* (B. Gaertner). Thus Scott, during the years 1923-34, investigated 186 outbreaks of food poisoning in this country. No less than 110 of these were caused by *Bact. typhi-murium*, while 19 were due to *Bact. enteritidis*, 16 to *Bact. thompson*, 13 to *Bact. newport*, and 8 to *Bact. cholera-suis* and its variety *Bact. cholera-suis var. kuzendorf*.

Many of these bacilli are well known as causing infections in animals, and though the consumption of meat from "emergency slaughtered" animals is rare in this country, in Germany, on the other hand, it is common, as is also the consumption of uncooked or partially-cooked meat. Thus Meyer, in 1929, reporting on the incidence of *Salmonella* food poisoning in Germany following the consumption of meat and meat products during the years 1923-28, alludes to 493 outbreaks, with 14,567 cases and 133 deaths; while Savage and White, from January 1921 to October 1923, reported 86 outbreaks in this country, with 2300 cases and 21 deaths.

Failure to recover bacilli of the *Salmonella* group from some cases of bacterial food-poisoning led Savage to suggest that some cases were caused by the ingestion of the products of previously existing bacilli, which had been killed in the preparatory processes, usually canning. This involved the existence of specific exotoxins in connection with the various bacilli involved, which, be it noted, were not limited to the *Salmonella* group. The symptoms of this "toxin" type of food poisoning tended to come on with less delay than was observed with infections with members of the *Salmonella* group, and the vehicle tended to be of the canned type, whereas the "infective" type was usually associated with more recently prepared foods. Moreover, in 1930 Dick and Jordan announced the discovery of cases of staphylococcal food poisoning. Since then many cases have been

reported. Most of these have followed the consumption of milk products, though some have been traced to gravy, canned meat, pressed beef or fish. No one type of staphylococcus has been involved; indeed, very few strains of staphylococci appear to have this property of toxin formation. That a preformed toxin is involved seems certain, in that the opportunity for the multiplication of the staphylococci before the consumption of the food is an antecedent necessity. The toxin is resistant to heat to such an extent that it is not completely destroyed by boiling for 30 minutes. It has very little effect on ordinary laboratory animals. Other cases of this type of "Toxin" food poisoning have occurred, due to such organisms as coliform bacilli in milk, and streptococci in fish, etc. Scott has suggested that about one-third of the reported outbreaks of food poisoning in this country are the result of staphylococcal intoxication, and Topley and Wilson suggest that another third may be due to other species of bacteria.

The general method of investigating outbreaks of food poisoning is described in a memorandum by the Ministry of Health (1935).

Chronic food poisoning differs from the epidemic type in that it is met with in individuals with no relationship, or no recent relationship, to epidemics of food poisoning. It is usually diagnosed in the laboratory, though a history of recurrent attacks of diarrhoea, or even of gastro-enteritis, perhaps over a number of years, and possibly dating from a typhoid-like illness may suggest to the clinician the presence of a member of the food-poisoning group of bacilli. Such infections are not infrequently met with in cases of colitis or "intestinal toxæmia," or may be disclosed in the routine examination of the intestinal contents, in which no intestinal symptoms exist. Such examination may disclose the presence of non-lactose-fermenting bacilli, and exploitation thereof by way of vaccine therapy may strengthen the hypothetical connection between the infection and clinical condition.

The variety of bacilli thus found in connection with chronic food poisoning is much larger than is the case with acute epidemic food poisoning, which, as shown above, tends to be confined to few types, viz. *Bact. typhi-murium* and *Bact. enteritidis*. A condensed table of the chief sugar reactions and characteristics of these non-lactose-fermenting bacilli is on next page.

The group of *Salmonella* bacteria typified by *B. paratyphosus* A and B, *B. typhi-murium* and *B. gaertner* constitute upwards of sixty named varieties of bacilli. Their ultimate classification depends upon the composition of their antigens—flagellar and somatic—indeed, their antigenic analysis.

The ultimate classification of any particular intestinal bacillus must rest upon specific serum agglutinations, antigen analyses and absorption tests. Such tests have differentiated from 60 to 70 varieties of bacilli in the "*Salmonella*" group alone.

The foregoing bacilli are the common abnormal bacteria found in epidemic and chronic food poisoning. The list is not to be taken as in any way exhaustive. There are, for instance, bacilli giving the sugar reactions of the paratyphoids which do not agglutinate with the specific sera of the members noted above, nor yet with a mixed *Salmonella* serum as issued by the Oxford laboratory, and yet which are controlled by an autogenous vaccine. There is more than one variety of Morgan's bacillus, and Castellani has described a *Bact. pseudo-asiaticus*, which ferments dulcitate, specimens of which are occasionally found in the human stool in this country. Again

426 DISEASES DUE TO PHYSICAL & CHEMICAL AGENTS

there appears to be a group of "late-lactose-fermenting" bacilli, which give the reactions of the Salmonella group, and after a lapse of perhaps 48 hours

	Lactose.	Glucose.	Mannite.	Dulcite.	Saccharose.	Indole.	Motility.	
<i>Bact. typhosus</i> . .	-	A	A	-	-	-	+	Described by Eberth in 1880. Cultivated by Saffrey in 1884.

lactose is fermented. Finally, there is a group which gives acid fermentation of glucose, mannite and dulcite, without gas, many of which are promptly controlled by the use of an autogenous vaccine.

In conclusion, it is to be noted that recently bacteria which are not normal to the intestines are much less frequently found than previously.

JOHN MATTHEWS.

Pathology.—The *post-mortem signs* are those of an acute gastro-enteritis, with evidence of a general bacterial infection or toxæmia. When diarrhœa has been very severe, the tissues of the body may be shrunken from drainage of fluid. Rigor mortis sets in early. The stomach may show some redness from congestion, and, especially where vomiting has been severe, there may be small submucous hæmorrhages. Much mucus is generally present, but the stomach contents are free from blood. The inflammatory signs in the small intestines are usually more marked than in the stomach, which is an important distinction from chemical irritant poisoning, such as that caused by arsenic. The mucous membrane is swollen and congested, and the lymphoid follicles and Peyer's patches often show marked swelling and congestion. The signs are often more marked in the ileum than in the upper part of the small intestine. The mucous membrane of the large intestine may be swollen and congested, and the lymphoid follicles much enlarged. The contents are liquid and may contain much mucus. Small submucous hæmorrhages may occur in any part of the intestinal tract. The spleen is congested and soft, and in cases where infection with living bacteria has occurred, it may be enlarged. The liver and kidneys may show cloudy swelling or fatty degenerative changes. It is important to remember that in fatal cases of food poisoning the macroscopic morbid changes found post mortem may be very slight. Cultures made from the blood in the heart, from the spleen, and from the intestinal contents may reveal the presence of food-poisoning organisms.

Symptoms.—*Latent period.*—The period which elapses between partaking of the contaminated food and the onset of symptoms may vary from a few hours to 3 or 4 days. Usually, however, the latent period is short, from 2 to 6 hours being common. The greater the amount of preformed bacterial toxins in the food, the earlier will be the appearance of symptoms. The latent period is influenced by other conditions. Thus, if the poisonous food is taken on an empty stomach, the symptoms will come earlier. Again, if the infected food is taken alone, the symptoms will occur earlier than if it is taken with a considerable amount of other wholesome food.

The symptoms are of sudden onset, and in some cases a rigor may usher in the attack. The symptoms are usually those of gastro-enteritis, namely, furred tongue, severe abdominal pain and a rise of temperature, and often vomiting and purging. The stools are liquid and very offensive, and sometimes contain mucus and blood. In severe cases there may be cramps in the calves of the legs, and collapse with heart weakness, and the patient may become cold and blue owing to the feeble circulation consequent on a state of extreme collapse. In some cases rashes appear of the type of "erythema," and in severe cases "purpura." Often the severe cases present the symptoms of bacterial infection of the blood (septicæmia) and such complications as pneumonia or toxic jaundice are then likely to occur. In some attacks of food poisoning, especially those due to contaminated fish, the toxins appear to act especially on the blood vessels, producing rashes with considerable

428 DISEASES DUE TO PHYSICAL & CHEMICAL AGENTS

swelling of the skin (erythema and urticaria), which are associated with fever and a furred tongue, though there may be but little or no diarrhœa and vomiting. In these cases, idiosyncrasy or allergy may play an important part.

Diagnosis.—The diagnosis is usually clear, from the sudden onset of typical symptoms a short period after taking contaminated food. A specimen of the stool should be taken for bacteriological examination in order to determine the presence of organisms of the *Salmonella* group, etc. A sample of blood should be taken for agglutination tests with organisms of the food-poisoning group, and the blood agglutination tests should be repeated after an interval of a few days, when a rise in the agglutination titre would be expected. It cannot be too strongly emphasised that the symptoms of bacterial food poisoning are almost identical with those of poisoning by arsenic or antimony or other chemical irritant poison. An analysis of the vomit, fæces and urine for arsenic and irritant chemical poisons at once renders the diagnosis clear.

Course and Prognosis.—In mild cases, the symptoms clear up in a few days and the patient is completely restored to health. Where there is an actual infection with living pathogenic organisms the illness may run a course similar to that of typhoid fever. Severe cases may present symptoms so acute as to resemble true cholera, and in these the prognosis is grave.

Complications and Sequelæ.—An attack of bacterial food poisoning may be complicated by the development of a specific disease, such as enteric or paratyphoid fever, owing to the living organisms of this disease being also present in the contaminated food. After an attack of bacterial food poisoning there is sometimes left a latent bacterial intestinal infection so that the patient, in addition to being a "carrier" of disease, is liable to recurring attacks of enteritis from slight causes.

Treatment.—**PROPHYLACTIC.**—The importance of this has been already indicated above. The greatest care should be taken in the avoidance of articles of food likely to be contaminated, and the efficient cooking of food whereby any living bacteria present are destroyed is a great safeguard. After cooking, rigid care should be taken in the storage of food to prevent contamination.

General treatment.—Rest in bed is essential. The diet should consist of liquids, such as water, albumin water, dextrose 5 per cent. solution in normal saline, chicken broth or whey. Milk is often best avoided; peptonised milk or citrated milk (2 grains of sodium citrate to the ounce of milk) diluted with an equal quantity of water may be given. The feeds should consist of 3 or 4 ounces of liquid every 2 hours, and to these 1 or 2 teaspoonfuls of brandy may be added with advantage. As the symptoms improve, the dietary is gradually increased. Hot applications to the abdomen are advisable. Where there is much pain and diarrhœa without collapse, the hypodermic injection of morphine is advisable. This may be given with advantage with atropine, *e.g.* morphine hydrochlor. gr. $\frac{1}{2}$, atropine sulph. gr. $\frac{1}{50}$. Colon irrigations with 2 pints of normal saline are of value in cases with diarrhœa and slight collapse. In cases with choleraic symptoms and marked collapse, subcutaneous or intravenous injections of normal or hypertonic saline should be given. (See Article on Treatment of Cholera, p. 129.) A mixture of bismuth and soda with hydrocyanic acid is of value in relieving the gastric irritation,

and to control the diarrhoea bismuth salicylate in 10 or 15 grain doses is useful.

The treatment of a case of food poisoning should be accompanied by periodical bacteriological investigations of the stools, and a case cannot be regarded as cured until three successive bacteriological examinations made at intervals of 2 or 3 days have shown freedom from infection with the pathogenic organisms of the disease.

DONALD HUNTER.

BOTULISM

Synonyms.—Sausage poisoning, Allantiasis.

Definition.—A rare, but very fatal form of poisoning due to the effect on the nervous system of the toxins of the *Bacillus botulinus*. Botulism belongs to the food-poisoning class of disease, but differs from the old conception of ptomaine poisoning, in which the actual poison was supposed to be altered food product, on the one hand, and from the bacterial food poisonings, in which an actual infection is transmitted, on the other hand. Ptomaine poisoning has now only historic interest, and the bacterial food poisonings fall into the group of infections known as enterica, in which a period of incubation is involved, and more or less symptoms of gastro-enteritis occur. Botulism depends upon the ingestion of a certain minute quantity of preformed toxin, and in no way upon the introduction of the bacillus or spores thereof.

Bacteriology.—*B. botulinus* is a large gram-positive bacillus, 4-9 μ long by 0.9-1.2 μ broad. It stains well with ordinary dyes, but tends to lose Gram's stain if care be not taken. It possesses flagella, and is slightly motile. It forms terminal or sub-terminal spores, especially, in the case of most strains, at a temperature between 20° and 25° C. Likewise the optimum temperature of growth for most strains is between 20° and 30°. The bacillus is a strict anaerobe, and will only grow in slightly alkaline or neutral media. In deep stab culture growth occurs as a thin whitish streak, not reaching to the surface; later the medium is cracked by the abundant formation of gas. With strict anaerobiosis the organism grows well on the ordinary media. Gelatine is liquefied. There are two types, A and B. They are readily separated by the fact that chickens are susceptible to type A only. Three different strains are named. They are the Boise (type A), the Nevin (type B), and the Memphis (type A). Type A is more common on the Pacific Coast of America, while type B is more common in the Eastern States, and in Europe. The strains differ in their behaviour to heat. Most strains are killed by boiling, but the Boise strain can survive boiling for an hour, and consequently steam pressures are necessary to sterilise adequately food products contaminated therewith. The toxins of the various strains all seem to be destroyed by temperatures slightly less than 80° C., the Boise strain toxin being destroyed by 10 minutes at 73° C. The toxicity of the toxin can be so high that 0.0001 c.c. of the filtrate of a culture grown at 35° C. proved lethal to a guinea-pig of 350 g. The Boise strain also differs from the others in that it grows best at or about body temperature, and has a characteristic odour.

Symptoms.—There being no incubation period, there are no symptoms prior to the onset of the dizziness and diplopia that constitute the first signs

of the involvement of the cranial nerves. Occasionally there are some abdominal pains, accompanied by vomiting, and there is some weight in the suggestion that the vomiting denotes an unusually heavy dose of toxin, for vomiting usually presages a fatal termination. Other cranial nerves are gradually affected, the larynx becomes involved and speech may be lost, and later respiration and the heart's action become affected, by reason of the involvement of the spinal accessory and vagus. Consciousness is not lost. Obstinate constipation is the rule, in sharp contrast to the diarrhoea usually associated with enterica. Botulism differs from encephalitis lethargica in that there is an entire absence of the somnolent state characteristic of the latter condition, while the absence of fever differentiates it from anterior poliomyelitis.

Prognosis.—This is very grave, the mortality being more than 50 per cent. In some outbreaks, for instance that of Loeh Marec, every case proved fatal. Death may take place in 36 hours, or may be delayed for a week.

Treatment.—Antitoxin given experimentally with toxin prevents the fatal effect of the latter. In practice, antitoxin treatment will only be available for use in the later or less severe cases of an outbreak. Measures to promote elimination of toxin are called for, but are handicapped by the obstinate constipation. Alcohol appears to have a distinct effect in "denaturing" the toxin, and may, therefore, be given freely, partly for this effect and partly for stimulation. Strychnine should also be given. Ether anaesthesia is said to delay fixation of toxin by the tissues, and if so it might be usefully employed while antitoxin was being procured. Some relief from the mental distress due to the absence of unconsciousness would also accrue.

JOHN MATTHEWS.

SECTION V

DISEASES OF METABOLISM

BASAL METABOLISM

By basal metabolism is meant the metabolism of an individual when he is lying down in as complete a condition of rest as possible, and has taken no food for 14 hours—the post-absorptive state.

Basal metabolism is increased by the intake of food, and the amount and nature of the food determines the amount of its increase. Exercise also increases metabolism, and considerably so. In order to obtain an accurate estimate, certain precautions are therefore necessary. It is customary to prescribe a light evening meal some 14 hours before the test, and to make the subject lie down, with the muscles in complete relaxation, for half an hour. The actual estimation may be performed in two ways, namely, by the direct method and by the indirect method, the latter being easier but not so accurate. In the direct method, the air which is breathed out under the standard conditions is collected in a Douglas bag for 10 minutes and the total volume measured. The amounts of carbon dioxide and oxygen present are estimated by means of a Haldane gas analysis apparatus. By this means the Respiratory Quotient (R.Q.), i.e. the ratio of the volume of carbon dioxide given out to the volume of oxygen taken in, and the amount of oxygen used may be determined with great accuracy. In the indirect method, the subject breathes oxygen which is in a closed system for 10 minutes. The carbon dioxide formed is absorbed with soda lime, and the oxygen which has been used is calculated from the amount of gas which has disappeared from the system. The surface area of the body in square metres is then estimated from the weight and height of the patient by means of the nomograph (Fig. 8). The amount of oxygen which has been used by the patient is then expressed in terms of one square metre of body surface per minute. The next step may be done in one of two ways. (1) The amount of oxygen per square metre of body surface is compared with the amount of oxygen which an average subject of the same age and sex consumes. (2) The number of heat calories which the oxygen would give when burnt under standard conditions is ascertained from the tables of oxygen values, and this result is compared with the calories per square metre of body surface which an average subject of the same age and sex would consume. The final result in either method is expressed as plus or minus x per cent. as compared with the average values in the case of normal people.

It is accepted that the subject is normal if the figure lies within the limits of plus or minus 10 per cent. Important variations occur when the thyroid is affected. If the gland is atrophied or absent (myxœdema), the basal rate may be as low as minus 40 per cent.; while if it is overactive

FIG 8.—BOOTHBY AND SANDIFORD'S NOMOGRAPH.

The weight in pounds or kilograms is shown on Scale I. The height in inches and centimetres is shown on Scale II. The surface area in square metres is shown on Scale III. The normal standard calories per square metre of body surface per hour are shown on Scale IV. The total calories per diem are shown on Scale V.

Directions.—Keep the chart flat. Use a flexible ruler with a straight edge, or a strip of stiff paper, such as a postcard. (A) Locate the position of the weight and height on Scales I. and II. respectively. Apply the straight edge of the ruler, and note where it cuts Scale III. Read the figure on Scale III., which will give the surface area of the body in square metres. (B) Locate the surface area on Scale III., and the normal standard calories per square metre per hour for the age and sex of the subject on Scale IV. Apply the straight edge of the ruler, and see where it cuts Scale V. Read this figure, which gives the total basal calories per 24 hours.

Large scale nomographs may be obtained from W. B. Saunders Co., West Washington Square, Philadelphia, U.S.A., or from H. N. Elmer, 1641 Monadnock Buildings, Chicago, U.S.A.

(exophthalmic goitre), the basal rate may be very high, varying from plus 15 to 20 per cent. to 100 per cent. or even more. In starvation and severe undernutrition, the basal rate will be below minus 10 per cent.

ACIDÆMIA AND ALKALÆMIA

Synonyms.—Acidosis, and Alkalosis.

Definitions.—*Acidæmia* signifies that there is an increase in the H-ion concentration of the blood. This may be due to an increase in the amount of CO_2 in the blood, or to an increase in the fixed acids of the blood. In the latter case, the acid unites with the bases and lowers the amount of CO_2 which can be carried in the blood. The name *acidosis* has been applied to this latter condition, but it has given rise to so much confusion that it is better to abandon the name altogether, and to speak of a decrease in the alkali reserve of the blood. *Alkalæmia* signifies that there is a decrease in the H-ion concentration of the blood. The name *alkalosis* has been used to describe the conditions in which there is an increase in the alkali reserve of the blood, but, for the same reason as for acidosis, it would be better to drop the name altogether, and to speak of an increase in the alkali reserve.

Physiology.—Normal blood has a pH which is slightly alkaline, and lies between 7.34 and 7.47 by the Hydrogen Electrode Method and 7.64 and 7.72 by the Indicator Method. (A neutral fluid has a pH of 7.07.) The figures for the Hydrogen Electrode Method will be used in this article.

The pH of the blood is kept very constant by the salts of weak acids, such as the acid and alkaline phosphates, and sodium bicarbonate, which, together with the hæmoglobin and proteins, act as "buffers" and prevent the reaction of the blood being easily changed. Further, other regulating mechanisms are at work, since urea can be split up into carbon dioxide and ammonia; the former can be excreted by the lungs, while the latter can be used to neutralise an acid. The kidney can excrete acid or alkaline salts which may be in excess, and thus help to keep the reaction of the blood constant.

Much attention has been paid to the regulation of the blood by means of the sodium bicarbonate and carbon dioxide. In this process, the respiratory centre plays a very important rôle, since, if it is damaged in disease or by drugs, such as morphine, the regulating mechanism is upset. When a fluid contains only weak acids and their salts, the H-ion concentration varies

according to the equation $(\text{H}) = \frac{(\text{H}_2\text{CO}_3)}{(\text{NaHCO}_3)} \times \text{K}$, when K is a constant, and the

brackets signify concentrations. If there is an increase in the H-ions of the blood, there must be an increase in the value of the fraction $\frac{(\text{H}_2\text{CO}_3)}{(\text{NaHCO}_3)}$,

since the value of K does not alter. The increase can be made in two ways, namely, either by decreasing the amount of NaHCO_3 , or by increasing the H_2CO_3 . If, on the other hand, the H-ion concentration is decreased the size

of the fraction $\frac{(\text{H}_2\text{CO}_3)}{(\text{NaHCO}_3)}$ is decreased, either by increasing the amount of NaHCO_3 , or by decreasing the H_2CO_3 .

The amount of NaHCO_3 present in the blood is termed the alkali reserve. This is estimated by measuring the CO_2 present in the blood or plasma which has been exposed to CO_2 at a pressure of 40 mm. of Hg. (Van Slyke's method). The figure for normal plasma is 55-70 vols. per 100 c.c. of blood (25-31.5 milli molecular equivalents). The estimation of the CO_2 in the alveolar air is also of assistance, since in health the CO_2 is present at the same tension in the blood and alveolar air. When the alkali reserve is reduced, there is usually a decrease in the percentage of CO_2 in the alveolar air, from the usual figure of 5 per cent., and this is sufficient to keep the fraction

$\frac{(\text{H}_2\text{CO}_3)}{(\text{NaHCO}_3)}$ constant, and so prevent any change in the pH. This will necessitate an increase in the volume of the respiration, as the same amount of CO_2 will be excreted under similar conditions of exercise and food.

In order to do this the respiration will be much deeper and is best illustrated by the "air hunger" of diabetic coma. If the breathing is not deep enough the pH of the blood will increase.

Acidæmia.—The amount of sodium chloride in the plasma is also important and varies between 560 and 622 mg. per 100 c.c. (96-106 milli molecular equivalents). There is a balance between the amount of alkali reserve and the plasma chlorides, and their sum varies between 121 and 137.5 milli molecular equivalents.

This is always due to an increase in the size of the fraction $\frac{\text{H}_2\text{CO}_3}{\text{NaHCO}_3}$, but may be caused in three different ways:

(1) A considerable increase in the H_2CO_3 of the blood together with a small increase in the alkali reserve. This occurs when the respiration centre is depressed, as in morphine poisoning, and needs more H_2CO_3 to stimulate it. There is usually a coincident increase in the alkali reserve, but this is less marked than the increase in the H_2CO_3 and an acidæmia occurs.

(2) An increase in the H_2CO_3 of the blood, with little or no change in the alkali reserve. This occurs when there is difficulty in getting rid of CO_2 from the blood, as in emphysema, bronchitis and asthma.

(3) A decrease in the alkali reserve, with little or no change in the H_2CO_3 . This condition may be due to many causes. The simplest are the giving of large amounts of acid sodium phosphate, calcium, or ammonium chloride to make the urine acid, with the result that the healthy kidney may be unable to excrete the acid salts at once. If the kidney is slightly damaged it may fail to excrete small amounts, while if it is seriously damaged acid salts will be retained as in uræmia and acidæmia will result. In diabetic coma and in the carbohydrate starvation which is found in cyclic vomiting, pernicious vomiting of pregnancy, and the mild vomiting after anaesthetics, the resulting ketosis is responsible for the acidæmia. It is believed that the

enolic group $\begin{array}{c} \text{COH} \\ | \\ \text{CH} \end{array}$ of aceto-acetic acid stimulates the respiratory centre.

Acidæmia of this type is also met with in gastro-enteritis. In all these conditions there is an increase in the depth of the respiration, most marked in diabetic coma (air hunger), but may be very striking in the other conditions. The pH of the blood may rise to 7.25 or 7.3, and the alkali reserve

may fall to 30 or 25 vols. of CO_2 per 100 c.c. (13.6–11.4 milli molecular equivalents) and the plasma chlorides will probably be increased to above 620 mg. (106 milli molecular equivalents); and the percentage of CO_2 in the alveolar air may be reduced to 2 or 1.5 per cent. If the vomiting is very severe and the ketosis slight the patient will develop an alkalosis.

Alkalæmia.—This is the opposite of acidæmia, and may be due to:

(1) A considerable increase in the alkali reserve, with little or no increase in the H_2CO_3 of the blood. This may be the result of the administration of large doses of alkali 12–20 g. (185–300 gr.) of sodium bicarbonate or its equivalent a day, as in the treatment of gastric ulcer. The symptoms in this case are loss of appetite, severe headache, irritability, restlessness and tetany. The condition may also arise if a patient suffers from severe vomiting, without ketosis, as in pyloric obstruction or high intestinal obstruction, and in young children with hypertrophic pyloric stenosis. In such the symptoms are due to the loss of the hydrochloric acid and sodium chloride present in the vomit, which outweighs the tendency towards acidæmia produced by the ketosis, and has most effect when, for some reason, ketosis has not occurred. In all these conditions the kidneys may fail to excrete urea and other substances, and the patient may die of uræmia, although the organs are not obviously diseased. The alkali reserve is high, and may be 80 or 90 vols. of CO_2 per 100 c.c. of blood 36–41 milli molecular equivalents, while the pH of the blood is less than 7.5. The plasma chlorides will be reduced below 560 mg. (96 milli molecular equivalents), in order to counterbalance the bicarbonate.

(2) A decrease in the alkali reserve with a considerable decrease in the H_2CO_3 of the blood occurs in people who live in high altitudes. If an individual ascends quickly, he will be cyanosed owing to the lack of oxygen and at first he will also suffer from dyspnoea. The lack of oxygen causes deeper respiration, and more carbon dioxide is washed out of the blood. Under these conditions the kidney excretes less acid and more ammonia, and the urine becomes alkaline. The loss of alkali causes a decrease in the alkali reserve, and at first suggests that an acidæmia exists. This is not the case, since the pH is decreased to, say, 7.5, thus proving that the loss of CO_2 is greater than that of alkali $\frac{(\text{H}_2\text{CO}_3)}{(\text{NaHCO}_3)}$. As the patient becomes acclimatised, the pH gradually rises to normal, although the cyanosis still exists.

Diagnosis.—This can be only made with certainty by employing the more accurate methods for determining (1) the H-ion concentration of the blood (Hastings and Sendroy), (2) the alkali reserve of the blood (van Slyke), (3) the plasma chlorides, (4) the reaction of the freshly passed urine, and (5) the amount of aceto-acetic acid and ammonia in the urine.

Prognosis.—This depends almost entirely on the nature of the disease causing the condition.

Treatment.—This should be directed to removing the cause of the condition. The treatment of the ketosis which occurs in diabetes is described on p. 454. In acidæmia, sodium bicarbonate, 31 (4 g.) 4-hourly, should be given for 3 or 4 doses, together with dextrose 1 oz. (25 g.) 4-hourly, with an abundance of water; in severe cases 1000 c.c. of normal physiological saline, or Ringer's solution, should be given intravenously by a continuous drip followed by 2000 c.c. of $\frac{1}{2}$ normal physiological saline, or Ringer's solution,

with 5 per cent. glucose in the 24 hours, provided that little or no fluid is taken by mouth. The treatment should, if possible, be controlled by estimations of the alkali reserve and the plasma chloride. Small doses of insulin, 10 to 20 units, may be of assistance. The bowels should be kept well open.

In alkalaemia, all alkalis should be stopped and acid sodium phosphate, gr. 30 (2 g.) 4-hourly, should be prescribed, besides sugar and water, as in acidæmia; in severe cases it is better to give 1000 c.c. of 10 per cent. glucose by a drip and a further 2000 c.c. if the patient takes little or no fluid by mouth. Here also treatment should, if possible, be controlled by estimations of the alkali reserve.

DIABETES MELLITUS

Diabetes mellitus is a disease in which the metabolism of carbohydrates, together with that of proteins and fats, is disturbed. The obvious signs of this are the presence of sugar and acetone bodies in the urine.

Ætiology.—(a) **PREDISPOSING CAUSES.**—Diabetes is more common among Jews than Gentiles, and in Frankfurt 31·5 per cent. of the cases were of Jewish descent. It is also very common in a mild form among the natives of India and Ceylon. Heredity undoubtedly plays some part, as many members of a family may be affected. This can partly be explained as being due to the same excesses of diet, especially when the disease develops late in life. But this cannot explain all the cases, especially those which occur among the younger members of the family. The familial form is sometimes very mild, but may be very severe. Joslin obtained a history of heredity in 20-30 per cent. of his cases. The inheritance of diabetes is probably a recessive characteristic. On this hypothesis, if two diabetics marry 100 per cent. of the children should develop diabetes, but so far only 8 out of 33 children, or 25 per cent., have done so; if a diabetic marries someone whose near relations have diabetes, 40 per cent. of the children should develop the disease, but only 48 out of 475 children, or 10 per cent., have been affected; and if two people whose near relations have diabetes marry, 16 per cent. of the children should become diabetic, but only 98 out of 2309 children, or 4 per cent., have had the disease. The discrepancy between the anticipated and observed figures is due to the short period in which the patients have been observed, many of them may develop the disease in old age. (White and Pincus.) Cases of diabetes in husband and wife occur occasionally, but this is probably due to similarity of living and not to contagion. The disease is more common among males than females up to the sixth decade, but in the higher decades there are more females than males affected. It is commoner between the ages of 40 and 60; these two decades contained 48 per cent. of Joslin's cases, while only 7 per cent. of the cases occurred between the ages of 20 and 40, and 4 per cent. were under 20.

(b) **EXCITING CAUSES.**—The disease is often present among elderly people who (1) take an excess of carbohydrate foods and sugar, (2) are considerably overweight, (3) have a blood pressure which is considerably raised. But the exciting cause of the acute disease which is seen in young people is quite unknown.

Pathology.—The blood contains sugar, and the amount varies in health between 80 and 120 mg. per 100 c.c. The total amount of sugar in the blood of a man weighing 65 kilos, or 10 st. 3 lb., would be 4 to 6 g. assuming that the total volume of the blood is $\frac{1}{13}$ th of the body-weight, i.e. 5000 c.c. The percentage amount of sugar in the blood remains fairly constant, so long as no food is eaten. A dose of 50 g. of dextrose will cause a rise in the blood sugar in the arterial blood, from 100 mg. to 150 or 180 mg. per 100 c.c. The change may be evident in 10 minutes, and usually reaches its maximum in 30 minutes. The sugar returns to its original level in a variable time—60, 90, 120 minutes, depending on the individual (Fig. 10). The sugar in the venous blood, after a carbohydrate meal, is about 20 mg. less than that in the arterial blood. Provided that the blood sugar does not exceed 180 to 200 mg. per 100 c.c. in the arterial blood, no sugar is excreted in the urine; but this depends on the level of the threshold of the kidney, as some people pass sugar at a lower level than 180 mg. per 100 c.c. (70–150 mg.), whereas others do not although the blood sugar rises to 250 to 300 mg. per 100 c.c. A carbohydrate meal produces a similar effect, but the rise is usually slower and more sustained. Protein does not cause any rise in the blood sugar of healthy people, but it does so in diabetic patients.

Some of the sugar which is eaten is burnt at once as the respiratory quotient approaches 1 after the dose of sugar, but the greater part of it must be stored, either in the liver or muscles. A healthy adult can usually eat 100 to 200 g. of pure dextrose without causing any glycosuria, but the individual variations are great.

In the mild cases of diabetes the blood sugar when fasting may be within normal limits, but a dose of 50 g. of dextrose will raise the blood sugar from 100 mg. per 100 c.c. to above 200 mg. per 100 c.c. The maximum height may be reached in 1, 2 or 3 hours, and then the blood sugar returns slowly to its original level (Fig. 11). Sugar is excreted in the urine all the time the blood sugar is above the threshold of the kidney for the individual, which may be about 180 mg. per 100 c.c. In the more severe cases the blood sugar is always above the threshold, and sugar is excreted throughout the day. In these cases there is a decrease in the power of burning sugar, and the respiratory quotient does not approach 1 after a meal, and may be below 0.8. When the carbohydrate metabolism is seriously upset, proteins also cause a rise in the blood sugar, as 58 per cent. of the protein molecule is burnt as sugar. The thirst of which the patient complains is due to the excretion of the sugar, as apparently this cannot be excreted without a good deal of water.

When the sugar cannot be burnt properly, the metabolism of fat is also upset, and the fatty acids, aceto-acetic acid, β -oxybutyric acid, are excreted in the urine. These are incomplete products of fat metabolism, and cannot be burnt completely in the absence of a certain amount of sugar metabolism. The amount of acetone excreted in the urine is a measure of the amount of aceto-acetic acid forms about 30 per cent. and β -oxybutyric acid forms about 70 per cent. of the total acetone bodies if these are present in large amount. The condition is normally called ketosis, instead of acidosis, as there is no acid gamma cell. In 1922, the concentration of the blood, unless deep coma or hypoglycaemia has been isolated, is normal. The amount of carbon dioxide in the alveolar air is normal in a depancreatized dog, and of pro-

FIG. 9.—A normal curve.

3 per cent., but this does not mean that the patient will pass into coma at once, but only that the condition is serious. If it falls below 2 per cent., the patient is usually comatose and is unlikely to recover unless insulin is injected in adequate amounts. The poisonous substance is probably aceto-acetic acid,

acting not as an acid, but through the enolic group $\begin{array}{c} | \\ \text{COH} \\ || \\ \text{CH} \\ | \end{array}$. This acts on the

respiratory centre (Hurtley and Trevan). The alkali reserve of the blood plasma is much reduced in severe cases and may fall from the normal 55 to 70 vols. per cent. (25–31.5 milli molecular equivalents) to below 20 vols. per cent.

The sugar metabolism is controlled by the internal secretion of four glands, namely, that of the islands of Langerhans, this being opposed by the suprarenal gland, the thyroid gland, and the posterior lobe of the pituitary gland.

The islands of Langerhans.—The relation of the pancreas to the metabolism of sugar has been recognised ever since von Mering and Minkowski, in 1889, showed that complete removal of the gland caused glycosuria and death of the animal. If, in a dog, the remnant be $\frac{1}{8}$ th to $\frac{1}{10}$ th of the whole gland, mild diabetes occurs; if less than $\frac{1}{10}$ th, severe diabetes results (Allen). The pancreas is made up of two glands:—(1) the acinous portion, which secretes the pancreatic juice through the pancreatic duct. It has no action on the sugar metabolism, since if it is entirely destroyed as a result of ligaturing the duct and replaced by fibrous tissue the sugar metabolism is quite unaffected so long as the islands of Langerhans are intact. (2) The islands, first described by Langerhans in 1869, are now recognised as definite entities, forming about $\frac{1}{100}$ part of the whole pancreas, and having an abundant blood supply. They contain three kinds of cells, called alpha, beta and gamma cells, which contain granules in their protoplasm as in the case of the gland cells of other organs. The alpha cells form about $\frac{1}{3}$ rd, and the beta about $\frac{2}{3}$ rds of the islands, while the gamma cells are few in number. The granules in the alpha cells stain differently from those in the beta and gamma cells, and these again stain differently from those in the acinous portion. Hence, if the tissues are fresh, the three kinds of cells in the islands can easily be distinguished from each other. When the surviving islands of a partially depancreatized dog are overworked by excessive sugar or carbohydrate feeding, only the beta cells are affected. The granules gradually disappear and a vacuole appears (hydrops of the cell). This process may continue until the cell finally consists of a large vacuole, with the nucleus flattened against one side, whilst all the granules have disappeared. Finally the cell breaks up and disappears. If the process is continued long enough the island will consist of alpha and gamma cells alone, and will be much smaller than usual. These experiments prove that it is the beta cells which control the sugar metabolism. The action of the alpha and gamma cells is unknown. The internal secretion of the beta cells had never been isolated until, in 1922, Banting, working with Best, succeeded in preparing an extract which had the power of lowering the blood sugar of a depancreatized dog, and of prolonging its life considerably.

Properties of insulin.—The extract of the islands of Langerhans is called insulin. It has been prepared in crystalline form, and 1 mg. contains about 25 units. Its constitution is not known, but the molecule must be very complex since it contains 23–24 tyrosine groups as well as some sulphur atoms. It has considerable capacity for binding acids, for it forms salts with hydrochloric acid, and has a greater capacity for binding bases. It is destroyed by pepsin, trypsin and alkalis, and therefore cannot be absorbed from the alimentary canal. Insulin enables the blood sugar to be kept within normal limits, and the liver and muscle to contain plenty of glycogen, so that the respiratory quotient will be about 1.0 and the fat correctly burnt. If insufficient insulin is present, the blood sugar will be increased in amount; the liver and muscles will contain little glycogen, the respiratory quotient will be about 0.7; and the urine will contain sugar and also acetone bodies, as the fats cannot be correctly burnt under these conditions. If there is excess of insulin the blood sugar will be small in amount; the muscles will contain plenty of glycogen, but the liver will contain very little. The precise way in which insulin acts is not yet understood, as it has no action on dextrose outside the body.

The potency of insulin is estimated by its power to lower the blood sugar of a healthy fasting rabbit or mouse to a certain level. The amount of insulin which lowers the blood sugar of a healthy fasting rabbit weighing about 2 kg. to 45 mg. per 100 c.c. in 2 hours is termed 2 units, and this represents about 0.04 mg. of the pure product. All the insulin prepared in this country has been carefully tested under the supervision of the Medical Research Council. It is dissolved in acid solution containing 0.5 per cent. of tricesol, and is of such a strength that 1 c.c. contains 20 units, 40 units (double strength), or 80 units (quadruple strength). It is put up in rubber-capped bottles, and does not deteriorate even in hot climates.

If too big a dose of insulin is given to a rabbit, the blood sugar will fall below 45 mg. per 100 c.c. and the animal may have convulsions and die. These symptoms can be relieved at once by the subcutaneous injection of 2 or 3 g. of sugar, unless the dose of insulin has been very large. Adrenaline, 1 in 1000, 0.3 c.c. (min. 5), or pituitary (posterior lobe) extract, 5 units (0.5 c.c.), will also relieve the symptoms at once. In human beings insulin acts in a similar manner, and if sufficient insulin is administered the blood sugar is always lowered. A dose of 5 to 10 units will lower the blood sugar of a healthy fasting adult of about 65 kilos to about 50 mg. per 100 c.c., but usually does not cause any symptoms of hypoglycæmia. Human beings, considering their much greater weight, are, therefore, much more sensitive to insulin than a rabbit.

When the blood sugar is raised, as in diabetes, the insulin causes a similar decrease in the blood sugar provided that a sufficient amount has been given. The extent to which the blood sugar is lowered varies in every patient and no definite law can be stated. The maximal decrease (Fig. 12) occurs about 3 to 6 or 9 hours after the dose, depending on the size of the dose of insulin, and may persist for about 10 hours, and after that the blood sugar begins to rise again. If the level of the blood sugar was above the threshold of the kidney for sugar the urine will contain sugar, but as soon as the blood sugar falls below the threshold the urine will not contain any sugar. If the urine is collected every hour and tested for sugar, it is possible to determine whether

the blood sugar has fallen below the threshold or not. If the blood sugar is lowered to about 50 mg. per 100 c.c., there may be symptoms due to the hypoglycæmia; but there is no definite level at which all patients develop symptoms, since some patients may feel quite well at this level whereas others, especially those who have had a high blood sugar for a long time, may experience severe symptoms although the blood sugar is 90 mg. or even 140 mg. per 100 c.c. The mild symptoms due to hypoglycæmia are a feeling of inertia, profuse sweating, tremor of the hands, and abdominal pain resembling hunger pains; and sometimes mild delirium and tachycardia may

FIG. 11.—Figure showing the effect of a dose of insulin on the blood sugar and urine sugar of a diabetic patient.

be observed. Rather more severe symptoms are numbness of the hands, face and tongue, diplopia and difficulty in articulation. Severe symptoms are: (1) A state of unconsciousness resembling a deep slumber from which the patient cannot be roused—the skin is usually very pale and the eyeball tension is raised. (2) Fits which may resemble epileptic fits; these occur chiefly in young children and only rarely in adults. (3) A state of inco-ordination of the muscles resembling locomotor ataxia.

The mild symptoms are easily relieved by glucose or a little cane sugar, orange juice, tomato juice, or some of the starchy food of the diabetic patient, provided that it is given as soon as the symptoms appear. The more severe symptoms are relieved at once if a sugar solution is drunk. If the patient is unable to swallow, adrenaline, 1 in 1000, 1 c.c. (min. 15), or pituitary (posterior

lobe) extract, 10 units (1 c.c.) will usually relieve the symptoms at once, but if the patient is deeply unconscious, 10-20 c.c. of a 25 per cent. solution of glucose (2.5-5 g.) should be given, intravenously, followed by 25 g. (1 oz.) of glucose or cane sugar by mouth as soon as the patient is able to swallow. If an intravenous injection is not possible, 50 g. (2 oz.) of glucose or cane sugar should be administered by a stomach tube, or 50 g. of glucose in 10 oz. of water as a retention enema.

The suprarenal gland.—The internal secretion of the medulla of this gland, called adrenaline, has a definite action on the sugar metabolism. If it is injected subcutaneously an increase in the blood sugar occurs, and glycosuria may occur if the level of the blood sugar is above the threshold of the kidney. An increase in the blood sugar also occurs when the splanchnic nerves are stimulated, and if the floor of the fourth ventricle is punctured, provided that the suprarenal glands are intact. Fear and excitement may also cause hyperglycæmia and glycosuria, e.g. Macleod's football players. It acts as an antidote to the excessive action of insulin. The gradual destruction of the suprarenal in Addison's disease reduces the level of the blood sugar slightly, and may cause attacks of hypoglycæmia, but an injection of adrenaline increases the blood sugar in the usual manner.

The thyroid gland.—This has some influence on the sugar metabolism, since the sugar tolerance is lowered when the gland is active, as in exophthalmic goitre, or if too much thyroid is administered. When there is atrophy of the gland, as in myxœdema, the sugar tolerance is increased.

The pituitary gland.—This gland plays an important part in the physiology of sugar metabolism. Houssay has shown that when the whole gland is removed from a dog and, on a subsequent occasion, the whole of the pancreas, hyperglycæmia and glycosuria do not occur, and the animal remains well. If afterwards an injection of an extract of the anterior pituitary gland is given to the dog, hyperglycæmia and glycosuria appear. If a healthy dog is given injections of the anterior pituitary extract, hyperglycæmia and glycosuria appear but tend to decrease in spite of daily injections of the extract. If the dose is then doubled, the hyperglycæmia returns but again tends to decrease. When the dose has been doubled 3 or 4 times, the dog develops a permanent hyperglycæmia although no further injections are given (Young). The dog's condition differs somewhat from that caused by the complete removal of the pancreas, as the animal remains well and ketosis does not develop. The dog eventually dies if no insulin is given, but responds to its administration and seems very well. The pancreas of a dog which has died usually shows widespread areas of fibrosis of the islands of Langerhans and contains 2-3 units of insulin instead of 80 units. The hyperglycæmia which occurs in some cases of acromegaly is probably due to an over-activity of the anterior lobe, and it is possible that this plays an important part in the causation of other cases.

Pituitrin, which is stored in the posterior lobe of the gland, has an important action in stabilising the level of the blood sugar. It prevents adrenaline causing an excessive rise of the blood sugar and also insulin causing an excessive lowering of the blood sugar. The injection of 10 units (1 c.c.) of pituitary (posterior lobe) extract is of great value in treating hypoglycæmia.

Morbid Anatomy.—The pancreas does not show any macroscopic changes. Warren found some fibrosis of the islets in 25 per cent. of diabetic patients

and it was extreme in 2·9 per cent. ; some hyalinisation in 37·8 per cent., and it was very definite in 15·5 per cent. ; in 25 per cent. of the patients, however, the pancreas appeared quite normal. Well-marked fibrosis and deposition of iron are seen in cases of bronzed diabetes, both in the liver and pancreas. Evidence of syphilis may be present ; Warthin found it at autopsy in 13 out of 14 cases, but in my experience it is rarely seen during life, only 3 out of 60 exhibiting the Wassermann reaction. The lungs may show the changes of broncho-pneumonia, lobar pneumonia or tuberculosis. If there have been nervous symptoms during life, there may be definite changes in the spinal cord, such as sclerosis of the posterior columns. There is no change in the sympathetic ganglia or in the pituitary gland. Atrophy or hypertrophy of the subcutaneous tissues may be seen at the site of the insulin injection.

LIPÆMIA.—In severe and advanced cases of diabetes the blood contains an excess of fat, either fatty acids or cholesterol. On separation of the corpuscles the plasma or serum has a pearly white appearance ; this is always a sign of the severity of the disease, but patients have occasionally made fair recoveries of sugar tolerance. The retinal vessels in lipæmia are very striking objects. In the less severe cases, the arteries and veins have a salmon pink appearance throughout their course. In the more severe cases, the vessels at the periphery become creamy white in colour, although near the disk, they are still salmon pink. In the severe cases, the distinction between the arteries and veins is completely lost and the vessels resemble flat ribbons. The vision remains unaffected.

Symptoms.—The onset of the disease may be very acute and great thirst is complained of ; the very day of onset of the thirst can sometimes be discovered. Some of these cases have died in coma, undiagnosed. More often the onset of symptoms is insidious, with lassitude, loss of energy, or pruritus, thirst not being a prominent symptom. In the mild cases, especially among elderly people, the diagnosis is usually made either in the course of a routine examination, or by accident, *e.g.* because of the complaint of white spots on the clothes or boots. In severe cases, thirst is the most troublesome complaint, and this necessitates drinking a great deal of fluid and passing a great deal of urine. The pruritus also troubles the patients, especially as the penis in males and the vulva in females are affected. Weakness is usually complained of, and sometimes a large appetite is a troublesome symptom. Constipation is usually present, and dates from the onset of the thirst in the acute cases. The tongue does not present any changes in mild or treated cases, but in severe and untreated cases it is dry and red—the so-called “raw beef” tongue ; this is only present when the patient is “desiccated,” as a result of great polyuria. There is usually great loss of weight. In the severe cases, the volume of the urine may be 4, 6, 8 or even 10,000 c.c. per diem, but in the treated case it is usually less than 2000 c.c. The specific gravity of the urine in the untreated case may be 1040 or 1050, depending on the amount of sugar in the urine.

Complications.—(a) *Coma.*—Formerly this was a frequent termination of the disease, but now it should only be seen in : 1. The very acute and the undiagnosed cases. 2. The severe and untreated cases. 3. As a terminal event as a result of any acute infection. Out of 9 cases of coma, 7 showed definite signs of a severe disease, 1 became comatose 7 days after the onset of the thirst, and in 1 no cause for the coma was discovered (Graham). There

are two main types, namely: (1) the hyperpnœa is well marked (air hunger), but the patient remains conscious until just before death; and (2) the hyperpnœa is not very obvious at first, but the patient becomes deeply unconscious a long time before death. More usually the patient shows a mixture of these two types. The blood pressure is low in both types, and the tension of the eyeball is very low. Constipation is always marked, and the contents of the intestines after death may be enormous.

(b) *Local infections*, such as boils and carbuncles, often occur, and the latter is often a fatal complication. Perforating ulcers of the feet occur in long-standing cases with signs of peripheral neuritis. Pigmentation of the skin, especially on the back of the hands, occurs in bronzed diabetes.

(c) *Atheroma* is more liable to occur in patients who have diabetes than in other people. It may be found in patients under the age of 30 who have had diabetes for some years. It more commonly occurs in patients between the ages of 60–70 who have had the disease for more than 10 years. This disposition to atheroma is perhaps due to the low carbohydrate-high fat diet used before 1930, and it is possible that the high carbohydrate-low fat diet now used will prevent the development of the disease. At present coronary disease giving rise to angina of effort and coronary occlusion is much more frequent in diabetics over the age of 50 than in non-diabetics, but the duration of life in patients with coronary disease is four years longer in the 1933–39 period than in 1923–26 (Joslin).

The cardiac condition is considerably aided by the skilful use of insulin, but severe attacks of hypoglycæmia should be avoided. The dread of these is often responsible for inadequate treatment of the diabetes, whereas adequate dosage of insulin will improve the cardiac condition (Joslin, E. P.)

(d) *Gangrene* of a limb, usually a leg, often occurs in elderly people. It is due to the associated arterial condition, and not primarily to the diabetic condition. Atheromatous changes in the arteries are present in many patients over the age of 40.

(e) *Pulmonary*.—Tuberculosis of the lungs is a common termination of the disease, and lobar and broncho-pneumonia are serious complications, as the patients pass rapidly into coma.

(f) *Renal*.—A trace of albumin is often present. Casts may be present in very large numbers in coma.

(g) *Nervous system*.—The knee-jerks may be lost early, but return if treatment is successful. Numbness and paræsthesia may be present, and the patients occasionally complain of a great deal of tingling pain in the legs and arms. Symptoms resembling those of tabes dorsalis and due to degeneration of the posterior columns may be present. The vibration sense is often diminished or even absent in the legs. The sensation of "hot and cold" may be lost, and this is associated with a lesion of the posterior nerve roots (radiculitis).

(h) *Eyes*.—A retinitis, which can be distinguished from albuminuric retinitis, is apt to occur in elderly patients. If the blood sugar remains high the condition tends to spread and may cause marked loss of vision, but if the blood sugar is kept normal the retinitis either spreads slowly or may even retrogress. Cataract is met with in elderly patients, and in young patients with severe diabetes, which is difficult to keep under control. Operations for cataract may be safely performed if the diabetic condition

is under good control. A retrobulbar neuritis may occur, especially in excessive tobacco-smoking. Lipæmia retinalis has already been described (p. 443).

(c) *Sexual functions*.—These may be undisturbed in the early stages of the disease, but the male may become impotent if the disease is badly treated. The female may become pregnant, but with care the pregnancy usually causes no untoward symptoms.

Diagnosis.—If the urine is tested the presence of a reducing substance is readily detected, but the nature of the reducing substance is less easily determined.

Fehling's solution is still commonly used, but the limitations of the test should be recognised. Equal quantities of solutions A and B should be freshly mixed, and equal quantities of urine and reagent boiled separately, mixed and not reboiled. If sugar is present in more than 0.5 per cent., the red precipitate comes at once, if in less than 0.5 per cent., it may not appear for one or more minutes. Fehling's solution is also reduced by glycuronic acid, uric acid, and creatinine. These substances are rarely present in sufficient amounts to reduce the copper solution, but when the urine is very concentrated they may cause a slight reduction.

Benedict's qualitative solution is not reduced by these substances. It is much more reliable than Fehling's solution and should replace it. Five or 3 c.c. of Benedict's solution and 10 or 6 drops of urine are boiled together for 2 minutes, or put in a boiling water bath for 5 minutes. If much sugar is present the precipitate develops on boiling, but small amounts may not cause a reduction before 2 minutes. The test will show the presence of sugar in a concentration of 0.08 per cent.

Benedict's solution is reduced by dextrose, lævulose, lactose, pentose and homogentisic acid (alkaptonuria), and special tests are necessary to distinguish these. Dextrose is dextro-rotatory, ferments with yeast, and yields crystals of glucosazone. Lævulose is lævo-rotatory, ferments with yeast, yields crystals of glucosazone, and gives Seliwanow's test. Lactose is dextro-rotatory, does not ferment with yeast, and yields a lactosazone with difficulty. Pentose is dextro-rotatory or optically inactive, is not fermented by yeast, and gives Bial's test. Homogentisic acid (alkaptonuria) reduces Fehling's and Benedict's solution to a deep brown colour; the urine blackens on standing, reduces an ammoniacal solution of silver nitrate to a black precipitate, and gives a momentary deep blue colour with the addition of a drop of very dilute ferric chloride. It does not ferment with yeast and is optically inactive.

If dextrose is present, disease of the other ductless glands and cerebral tumours should be excluded. The pigmentation of the skin of the body and of the backs of the hands, together with an enlarged liver (bronzed diabetes), should be looked for. Acute and chronic pancreatitis should be thought of before the diagnosis of a primary lesion of the islands of Langerhans is accepted. The diagnosis should always be confirmed by estimating the blood sugar before any change is made in the diet. The blood should be collected about 2 hours after a starchy meal, and if it is over 200 mgs. per cent. per 100 c.c., the patient has diabetes. If it is less than this figure and if glycosuria has occurred in the previous two hours a complete test of the sugar tolerance, with estimation of the blood sugar every half-hour for 2

hours after a dose of sugar, in order to exclude the possibility of renal glycosuria (see p. 456).

TESTS FOR ACETONE BODIES.—*The ferric chloride test.*—Add the solution drop by drop until all the phosphates are precipitated. As soon as this occurs, a violet colour appears if aceto-acetic acid is present in the urine in any quantity. This is a test for aceto-acetic acid, which can be detected in watery solutions in a dilution of 1 in 100,000. In urine, however, the test is much less delicate, owing to the interference of the pigments in the urine. The presence of sodium salicylate in the urine may cause confusion, but the colour produced in this case is purple. The distinction can be made by boiling the urine with a little weak acetic acid, and repeating the test when the urine is cold. The aceto-acetic acid distils away, whereas the sodium salicylate is unaffected by the boiling. This possibility of confusion is avoided by always using Rothera's test.

Rothera's nitroprusside test.—Saturate the urine with ammonium sulphate crystals, add 2 c.c. of liquor ammoniæ fort., and then a few drops of a fresh solution of sodium nitroprusside. If a little aceto-acetic acid is present, the permanganate colour develops slowly; if a great deal, the colour develops instantaneously, and it is impossible to see through the mixture after 10 to 30 seconds. When the nitroprusside reaction is strongly positive, the urine should be diluted 1 in 5. If the colour still appears instantaneously and deepens rapidly there is a large amount of aceto-acetic acid present. Aceto-acetic acid can be detected in a dilution of 1 in 400,000, and acetone in a dilution of 1 in 10,000.

There is no colour test for β -oxybutyric acid, but it is always present when more than 2 g. of aceto-acetic acid are excreted per day.

Prognosis.—This depends, as in the case of other diseases, on the severity of the attack, the time which has elapsed between the onset of the disease and the commencement of treatment, the skill of the medical adviser, the care with which the patient follows the directions given and the complications which occur. The attack is more likely to be severe in young people, but quite mild cases are often seen. In elderly people mild attacks are the rule, but severe attacks also occur. The prognosis had been much improved by the new dietetic treatment introduced in 1915. But although the prospects of life for several years were much better than they had been, the outlook remained a gloomy one for the patient with a severe form of the disease. The introduction of insulin has greatly improved the chances of life of all patients with any form of diabetes, but especially in the case of those with the severe forms. How much longer these patients will live it is impossible at present to say, but probably for many years, provided no complications occur. Out of 98 patients admitted to hospital in 1923 and 1924, 55 were alive at the end of 1931, and 47 at the end of 1935. Insulin has completely altered the prognosis in the case of pregnancy. The risks usually attendant on the pregnancy and puerperium constitute the chief danger.

Treatment.—The general health of the patient should be treated. Any sources of infection, such as pyorrhœa, cholecystitis and boils, reduce the sugar tolerance considerably. The possibility of syphilis should also be inquired into, and, if necessary, treated.

Although the introduction of insulin has altered the prognosis, it has not altered the principles of treatment which had been in use previously. Great

attention has always been paid to diet, but under the stimulus of insulin much more attention is being devoted to it. The principles which govern treatment are: (1) the blood sugar of the patient when fasting should if possible be within the normal limits of 80 and 120 per 100 c.e., and should not rise above 190 per 100 c.e. at any time of the day. It follows from this that the urine should never contain any sugar; but this is only possible in the patients who need little insulin and in elderly people. (2) The urine should not contain aceto-acetic acid. (3) The patient should understand that a large portion of the reserve power of the islands of Langerhans has been lost, and that additional insulin will probably be required whenever the patient has another illness.

Diet.—Although the principles of treatment have not altered, the details have changed considerably since the discovery of insulin. Allen, with his under-nutrition diet made a great advance, but this treatment should not be used nowadays except for patients who are very much overweight. One fast day on which no food except tea, coffee with a little milk, lemonade or meat extracts are taken, followed by a diet containing 100 g. of carbohydrate, 50 g. of protein and 50 g. of fat, calories 1080 (Example 1) may get ride of the glycosuria and lower the blood sugar to normal limits in mild cases. If the patient is grossly overweight the fast day can be repeated with advantage at intervals of one to four weeks, so as to make the patient lose weight. All other patients, especially those under 50 years of age, should start the treatment with a good diet and have insulin if the blood sugar remains above normal limits. The initial carbohydrate intake should be at least 150 g. unless the patient is very old and has a small appetite; it should be increased to 200, 250 or 300 g. according to the age and activities of the patient. Children under 12 are usually satisfied with 150 g. of carbohydrate, but those over 16 need 250 to 300 g. until they have passed the maximum calorie requirements, which occurs at the age of 16 to 18. The amount of protein should be about $\frac{1}{2}$ g. per lb. of body weight, but the elderly need less than this and can be trusted to gauge it by their appetites and should not eat more than they wish. Children at the age of 12 require 1 g. protein per lb. body weight; at 6 require 1.5 g. protein per lb. body weight; and at 2 require 2.0 g. protein per lb. body weight. The amount of fat in the diet should not be more than 100 g. and at the beginning of treatment should be less than this, say 50–75 g. The calorie content of a diet containing C. 150, P. 70, and F. 100 is 1832, and 2242 when 250 g. carbohydrate is given. This is a low figure compared with 3000 calories, which is regarded as the average requirement, but it is surprising how many patients maintain and even gain weight on these relatively small amounts of food. This suggests that the anterior lobe of the pituitary may play an important part in the disease. If the patient gains too much weight, the fat and protein and perhaps the carbohydrate should be reduced. If the patient loses weight, the carbohydrate should be increased by 30 g. and the dose of insulin increased by 6 or 8 units. A sample diet containing about C. 150 g., P. 70 g. and F. 100 g. calories 1832 is shown (Example 2), and the patient should learn how to vary the diet with the aid of the Food Tables 1 and 2 (p. 451). It is important that the amount of carbohydrate at each meal should be kept as constant as possible. When the carbohydrate of the diet is increased above 150 g., the extra carbohydrate should be divided equally between the three main meals of the day. The

so-called diabetic breads or cakes should not be used, as one ounce of some of them contains 10-12 g. of carbohydrate and extra protein compared with the 15 g. of one ounce of white or brown bread. Diabetic jellies, jams and marmalade all contain a little glycerine, but the amount is so small that it can be neglected.

Insulin should be given (1) to the fat and elderly patient who is having 100 g. of carbohydrate if the glycosuria does not disappear or returns after it has once disappeared. The amount of carbohydrate should not be reduced in these cases, but the effect of an occasional fast day may be tried before insulin is started. (2) To the thin and to all young patients who are given a diet containing 150 g. of carbohydrate.

The diabetic condition should be controlled first of all with the ordinary soluble insulin, as this is easier to use than the insulins whose action is

For permission to reproduce these two Diets, which were originally published in my article on *An Index of Treatment*, I am indebted to the courtesy of the present editor, Dr. Reginald King, and the publishers, Messrs. John Wright & Sons, Ltd.]

prolonged by the addition of a protamine or globulin together with zinc. The patient can be treated at home if the condition is mild; if it is more severe a nurse should be in charge of the patient; while in the very severe cases it is essential that the patient should be under close supervision with a day and a night nurse.

The dose of insulin can be determined by the results of the urine tests provided that the specimens are collected every three hours approximately and tested with Benedict's solution; the results should be charted. It is sometimes essential and is always an advantage to estimate at intervals the blood sugar before the injection, and 4 and 10 hours after it. This should be repeated if necessary, or the blood can be collected at one of these times only depending on the results of the urine tests and the presence of hypoglycæmia. In a mild case an initial dose of 10 units may be sufficient to render the urine sugar-free throughout the day after 3 or 4 doses, but it is usually necessary to give an evening injection of 6 units. If the clinical condition is not urgent each dose should be increased by 2 units every 2 or 3 days until the urine is sugar-free part of the day. When this occurs the morning dose should be increased by 2 units every 3 days as long as the urine before the evening injection contains sugar, and the evening dose should be increased by 2 units every 3 days so long as the urine before the morning injection contains sugar. When the urine is sugar-free throughout the day the patient may have signs of overdosage, *i.e.*, hypoglycæmia, some 4 to 6 hours after the injection. He should be warned about the symptoms and their treatment with sugar (see p. 441), and the dose of insulin which caused the hypoglycæmia should be reduced the next day by 2 or 4 units according to the severity of the attack. If this is carried out intelligently the dose of insulin may be reduced very considerably or even given up altogether. In the latter event, the urine after the evening meal should be tested and if sugar reappears for 3 days consecutively 4 or 6 units of insulin should be given before breakfast and if necessary increased until the urine is again sugar-free.

When the condition is severe from the beginning, it is necessary to increase the dose of insulin quickly, and the following procedure is free from danger. If, for instance, the dose of insulin is 24+12 units with every specimen showing a red test with Benedict, give 8 units immediately before the midday meal, provided the test from 11-1 is red or yellow; and increase the evening dose by 4 units and the dose the next morning by 8 units. This procedure is followed each day, keeping the "extra" dose about $\frac{1}{3}$ rd the size of the morning dose and adding half the "extra" dose to the evening injection, provided the urine from 5-7 p.m. gives a red or yellow test, and adding the whole of the "extra" dose to the morning injection so long as the urine before the injection gives a yellow or red test. In this way the dose of insulin can be rapidly increased to 100, 200 or 300 units if necessary. It is usually possible to administer 2 doses only once the diabetic condition is controlled, and the dose of insulin in some cases may be decreased very rapidly.

Active exercise often causes hypoglycæmia, and it is advisable either to decrease the morning insulin by 5 units or more, or to take extra carbohydrate 10-15 g. in the middle of the morning if the exercise is taken in the morning; extra carbohydrate should be taken at tea-time when the games are played in the afternoon or evening.

TABLE 1—CARBOHYDRATE

The following articles of food contain approximately 5 g. of carbohydrate, and may be substituted for each other without causing serious error.

A. VEGETABLES

Group 1—

(These need not be weighed as they contain so little carbohydrate):

Asparagus	16 oz.
Cabbago	18 "
Cauliflower	15 "
Celery (raw)	14 "
Cucumber (raw)	9½ "
French Beans	16 "
Lettuce (raw)	9½ "
Mustard and Cress	20 "
Rhubarb	18 "
Radishes (raw)	6½ "
Sea-Kale	29 "
Spinach	13 "
Watercress (raw)	25 "
Brussels Sprouts	10 "
Marrow	13 "

Group 2—

Beans, broad	2½ oz.
Beans, Haricot	1 "
Beetroot	2 "
Carrots	4 "
Leeks	4 "
Onions	6 "
Paranips	1½ "
Peas (dried)	1 "
Peas (green)	2 "
Potatoes	1 "
Turnips	7 "

B. FRUITS

Apple (raw)	2 oz.
" (cooked)	4 "
Apricot (fresh, with stone)	3 "
Banana	1 "
Blackberries	3 "
Cherries (with stone)	1½ "
Damsons (with stone)	2 "
Gooseberries (raw ripe)	2 "
" (unripe, stewed)	10 "
Grape Fruit	3½ "
Grapes	1 "
Greengage (with stone)	1½ "
Melon	3½ "
Oranges	2 "
Peaches (with stone)	2 "
Pears	2 "
Pineapple (fresh)	1½ "
" (tinned)	½ "
Plums (with stone)	2 "
Raspberries	3 "
Red or Black Currants	3½ "
Strawberries	3 "
Tomatoes	6 "
Jam or Marmalade	¼ "

C. NUTS

Almonds	1 oz.
Chestnuts	½ "
Hazel Nuts	1½ "
Walnuts	1½ "

D. STARCHY FOODS

Milk	3½ oz.
Bread	½ "
Dry Oatmeal	½ "
Force or Cornflakes	½ "
Rice	½ "
Plain Biscuit	½ "

The following contain little or no carbohydrate :

Tea	Lemon Juice	Meat Extract	Vinegar
Coffee	Soda Water	Gravy Soup	Saccharine

TABLE 2—PROTEIN AND FAT

The following articles of food contain approximately 6.5 to 7.0 g. protein, and 6.5 to 7.0 g. fat, and may be substituted for each other without causing serious error:

1 oz. Beef.	1 oz. Rabbit, with the addition of ¼ oz. Butter.
1 " Mutton.	1 " White Fish, with the addition of ¼ oz. Butter.
1 " Pork.	1 " Ham.
1 " Lamb.	1 " Cheese.
1½ " Tripe.	1½ " Bacon, but ½ oz. Butter should be deducted from the Butter ration.
1 " Veal.	2½ " Bread.
1 Egg.	6 " Milk.
1 oz. Sardines.	Fat, 5 oz. cream=1 oz. Butter.
1 " Salt Herring.	
1 " Salmon.	
1 " Chicken with the addition of ¼ oz. Butter.	

1 g. Protein	=4.1 Calories.	6.25 g. Protein	=1 g. Nitrogen.
1 " Carbohydrate	=4.1 "	1 kg.	=2.2 lb.
1 " Fat	=9.3 "	30 g. or cubic centi-	
1 " Alcohol	=7 "	metres (c.c.)	=1 oz.

A patient at rest requires 25 calories per kilo body-weight per 24 hours, approximately 1 calorie per kilo per hour.

Some patients do not recognise the signs of hypoglycæmia and become unconscious or have epileptiform fits. They may be helped by a change from the quick-acting insulin to one of the slow-acting insulins, or vice versa. If this procedure fails it is essential to reduce the dose of insulin and allow a little glycosuria to occur before each dose of insulin, but the urine passed between 1 and 5 p.m. should be free from sugar. It is important to discover the level of the threshold of the kidney in these cases, as the glycosuria may be due to the low threshold and not to a high blood sugar.

The New Insulins.—Intensive research work on the properties and preparation of insulin has resulted in three new preparations: Protamine insulin (trade name Delay), introduced by Hagedorn; protamine insulin with zinc, prepared by Scott; and globin insulin with zinc. The protamine insulins are milky suspensions, but globin insulin is a clear solution. Protamine insulin has no immediate effect on the blood sugar, but begins to work after 4 hours or so, and its effect lasts for 8 to 12 hours. Protamine insulin with zinc does not have any effect for the first 8 to 12 hours, but it continues to act for 24 to 28 hours. Globin insulin begins to act a little sooner than protamine zinc insulin, but otherwise its action is very similar. The protamine insulin with zinc and globin insulin either alone or in combination with ordinary insulin, will often control the blood sugar by means of only one injection in the morning. If a patient is well balanced on 20 units in the morning and 16 units at night, the change should be made to 20 units of ordinary and 12 units of protamine insulin with zinc or globin insulin; the reduction of 4 units is necessary to prevent the patient having overdosage, as the mixture is more efficacious. The insulins may be mixed in the syringe and administered in one injection. The patient is then liable to hypoglycæmia at three times in the day—before the midday meal as the result of the ordinary insulin, before the evening meal due to the protamine insulin with zinc beginning to act, and during the night when it is very active. This last reaction may come either early in the night or as late as just before breakfast. The amount of carbohydrate should be adjusted to overcome this liability to overdosage. An extra 10 or 15 g. should be given at tea-time, before going to bed, and before the morning injection of insulin. This will entail an increase of between 30 and 45 g. of carbohydrate, but this is usually well tolerated in spite of the initial reduction of the dose of insulin. The change is facilitated by the estimation of the blood sugar, but it can be achieved without this if the urine is tested regularly every 3 hours during the day, on waking, and before breakfast is eaten.

RULES FOR DECREASING THE INSULIN IN CASES OF OVERDOSAGE

- (1) If there are any signs of overdosage at midday, the dose of ordinary insulin should be decreased by 2 units, or if severe by 4 units.
- (2) If there are any signs of overdosage between midday and the evening meal, the dose of each insulin should be reduced by 2 units, or if severe by 4 units.
- (3) If there are any signs of overdosage between the evening meal and the next morning, the dose of protamine zinc or globin insulin should be diminished by 2 units, or if severe by 4 units.

RULES FOR INCREASING THE DOSAGE OF INSULIN

- (1) If the urine passed at 8 a.m. contains sugar, it means that the dose of protamine zinc or globin insulin was insufficient and should be increased by 2 units every third day if necessary.
- (2) If the urine passed at 7 p.m. contains sugar, it means that the dose of ordinary insulin was insufficient and should be increased by 2 units every third day.

The proportion of the two kinds of insulin varies, for in some cases equal amounts of ordinary and protamine insulin with zinc or globin are needed, while in others much ordinary and little protamine, or little or no ordinary and much protamine insulin with zinc, are necessary. Some patients can be well controlled with the mixture of insulins, and the doses of the insulins can be gradually reduced. If the case is difficult to control, the patient should be allowed to pass sugar before breakfast and before the evening meal. In these cases better results can often be obtained with a mixture of protamine (Delay) and ordinary insulin twice daily, as this is equivalent to giving four doses of insulin a day. Thus, if a patient is passing much sugar at 8 a.m. and yet after 30 units of ordinary insulin has symptoms of hypoglycæmia at midday and again passes much sugar at 7 p.m., he can be helped if the dose of ordinary insulin is reduced to 20 units and 10 units of delay administered at the same time. This will prevent the hypoglycæmia at midday, and also tend to prevent the blood sugar from rising so high at 7 p.m. Similarly, if the blood sugar is very low at night and high before breakfast, the evening dose is diminished by 10 units and 10 units of delay insulin are given. By varying the dose of the two different kinds of insulin it is often possible either to control the glycosuria and hypoglycæmia completely, or to lessen considerably the inconvenience of the attacks of hypoglycæmia. It is not possible to say which combination of ordinary and delay insulin will be most effective, as this can be discovered only by trial and error. Some patients need a mixture of both insulins night and morning; others, delay at night and a mixture of the insulins or ordinary only in the morning; and others, either a mixture of the insulins or delay alone at night, and another combination will be necessary in the morning.

Further advances with the different kinds of insulin may be expected, and the lot of the diabetic patient will consequently be further improved.

The *after-treatment* is very important. The patient should be taught as much as is possible about the disease and diet, for if he understands the principles concerned, he is much more likely to carry out the treatment correctly. He should also be taught to test the urine with Benedict's solution. If no insulin is taken the urine passed after the evening meal should be tested, but if insulin is used the urine immediately before the injection in the morning or evening should be tested.

Medicinal treatment.—Many preparations of the pancreas or of herbs which can be taken by mouth are extensively advertised. With one exception they are all valueless as well as being expensive. Synthalin, 40 mg., with decholin, 25 mg., given for 3 days at a time with one day's rest, has a definite though slight action on the glycosuria and glycæmia in many

cases. It has the great disadvantage that it often causes toxic effects, such as dyspepsia, vomiting and jaundice. It should not be recommended unless the patient refuses insulin. Laxatives are of great importance, and the necessity of an efficient daily evacuation should be insisted on. Ext. aloes, gr. 4, ext. nuc. vom., gr. $\frac{1}{4}$, in pill form, one to two at night; inf. of senna pods, ten to thirty; phenolphthalein gr. 4 to 8 or more in liquid paraffin 1 fl. oz. b.d.s., are the most efficacious; salines, together with tinct. jalapæ eo. min. 30, should only be used in emergencies. General tonics which improve the health may be used. Opium used to be of assistance in the late stages of the disease, but should not be given nowadays.

Complications—Coma.—This requires prompt and energetic treatment with large doses of insulin. The patient is sometimes very cold and collapsed, and he should be made warm as soon as possible, by means of a hot air bath, or, if this is not available, by hot water bottles, as in the treatment of surgical shock. The blood sugar is usually high, 300–800 mg. per 100 c.c., and it is safe to give 50–100 units of insulin, subcutaneously, as soon as the diagnosis is made without waiting for a blood-sugar determination. If the condition is very grave, the insulin should be given intravenously. If it is not possible to estimate the blood sugar, a dose of 50 g. (2 ounces) of dextrose should be given by mouth or by an œsophageal tube, and 50 to 75 units of insulin (Fig. 11). If there are no signs of returning consciousness in 3 hours, another 50 or 70 units of insulin, together with 50 g. of dextrose in solution, should be given. The urine should be collected every 3 hours. If it is necessary to pass a catheter, a self-retaining one should be used and the urine tested every hour. The urine for the first 3 hours after insulin is certain to contain sugar, and if the urine for the 4th to 6th hours contains sugar, it is safe to give 30 to 50 units of insulin. If, however, the urine for the 4th to 6th hours does not contain sugar, it is dangerous to give any more insulin, unless sugar, in the proportion of 4 g. to 1 unit of insulin is given by the mouth or intravenously at the same time. If there is any doubt as to whether the patient is recovering, this latter procedure should always be followed. If the condition, however, is improving, no insulin should be given until sugar reappears in the urine. Water in as large amounts as is possible, either by mouth or by nasal catheter, should be given; at least 10 ounces each hour for some 6 hours. If the condition is grave, especially if the patient is vomiting, the fluid should always be administered by an intravenous drip. A solution of 10 per cent. dextrose in $\frac{1}{2}$ normal physiological saline should be given. 2000–3000 c.c. should be administered in 24 hours if nothing is taken by mouth. An estimation of the hæmoglobin should be made at intervals, in order to determine whether sufficient fluid is being given or not. Two ounces of castor oil should be given with the first drink, as these patients are nearly always very constipated. In coma the alkali reserve is always much reduced, and sodium bicarbonate is of assistance, although the enormous doses which were administered before the discovery of insulin should not be given. A dose of 12 g. (3 drms.) 600 c.c. of 2 per cent. sodium bicarbonate should be given intravenously, or 4 g. by mouth every 4 hours for 4 doses.

Every patient who has been in coma should be examined most carefully, in order to determine whether any other disease is present. In 7 out of 9 cases admitted to St. Bartholomew's Hospital in the first year of insulin treatment, an acute infection, e.g. acute otitis media, parotitis, or gangrene of the lung,

was present. The appropriate treatment should be instituted as soon as possible.

Acute infections, such as influenza, usually cause a considerable diminution of the sugar tolerance. If the infection is of mild degree, it may be sufficient to increase the dosage of insulin by 2 or 4 units for some days. The insulin must never be omitted, though half the dose should be given if the patient vomits or cannot take food. If, however, the infection is of severe degree, it is important that the condition should be adequately treated, so as to prevent (1) any danger to life, and (2) any permanent diminution of the sugar tolerance. The same procedure should be adopted as in the treatment of coma (Fig. 12), but the dose of insulin should be much smaller, unless the patient is very ill. Provided the urine is collected in 3 hourly periods and tested for sugar, a sufficient dose of insulin may be given with safety every 6 or 9 hours, and thus the ill-effects of the infection reduced as much as possible.

Surgical operations were always contra-indicated before insulin was

FIG. 12.—Figure showing how an adequate dose of insulin can be arrived at by testing the urine in a patient in diabetic coma.

known, but they may now be carried out, provided certain precautions are observed. The patient's blood sugar should be reduced to normal, provided that there is time to achieve this. Gas and oxygen, local or spinal or intravenous anaesthetics cause no ill-effects. Neither ether nor chloroform should ever be given alone, but the former may be given with gas and oxygen, if deep anaesthesia is required, but as little as possible should be used. Fifty g. (2 oz.) of sugar, together with 16 units of insulin (1 unit to 4 g.), should be administered about 2 hours before the operation, in order to have plenty of sugar and insulin in the body at the time of operation. If the patient is having insulin and a diet containing 150 g. of carbohydrate, and the diabetic condition is under good control, the usual dose of insulin should be given four hours before the operation and 2 oz. of sugar half an hour later. If the diabetic condition is badly controlled, the operation should be delayed if possible, but in an emergency the dose of insulin should be increased by an extra 8–12 units, and special care must be taken after the operation, and estimations of the blood sugar should be made more frequently. After the operation the appropriate diet for the surgical disease, together with adequate amounts of insulin, should be given for the first few days, but as soon as possible the usual diabetic diet should be given and the blood sugar controlled again. If

pregnancy occurs it should not be terminated unless there are other complications.

RENAL GLYCOSURIA

This is an uncommon condition which is apt to occur in several members of a family. Although the blood sugar lies within normal limits, dextrose may be present in the urine, either throughout the day or only after a carbohydrate meal. The sugar is usually small in amount, *i.e.* less than 10 g. per diem, but several cases are reported in which 20 to 30 g. were excreted in the day. The amount of sugar in the diet has little influence on the total sugar excretion. The diagnosis should only be made after a series of observations. A complete test of the sugar tolerance with a dose of 50 g. of sugar should be made when the patient is eating plenty of carbohydrate food and the urine contains no acetone bodies. Estimations of the blood sugar should be made at intervals of half an hour for 2 to 3 hours after the dose of sugar, and the amount of sugar excreted in the urine should be estimated. If sugar is present in the urine, although the blood sugar does not rise above 180 mg. per 100 c.c. at the end of 30 minutes and has returned to the normal level after 2 hours, the patient probably belongs to the renal glycosuria class.

The prognosis is good, and no treatment is required once the diagnosis is made. It is wiser to treat all doubtful cases with moderate restriction of the carbohydrate ration (150 g.) and to repeat the sugar tolerance test in 1 to 3 months' time. Very little harm can be done by this procedure, while much damage can be done if a case of true diabetes is treated with no dietetic restrictions (Salomon, Graham).

THE LAG OR STEEPLE CURVE

In some cases the blood sugar rises to 250 mg. per 100 c.c. after 30 minutes, but returns to 200 mg. after 60 minutes and to less than 130 mg. in 90-120 minutes. Sugar is excreted in the urine in the first and second hours. This is also considered an innocent curve, has a good prognosis, and requires no treatment. Patients with renal glycosuria or lag curves are as liable, but no more liable than anyone else to develop diabetes in the future.

LÆVULOSURIA

Lævulosuria is a sign of some derangement of the liver and should direct attention to that organ. Slight reduction of carbohydrates and of fruits is usually sufficient to check it.

LACTOSURIA

This occurs (1) during lactation, (2) when suckling suddenly ceases, and (3) in breast-fed infants with enteritis.

PENTOSURIA

This is a rare occurrence. Many of the patients are Jews. Of 7 cases 3 were Jews, 2 Greeks, and 2 English (Cambridge).

SPONTANEOUS HYPOGLYCAEMIA

Synonym.—Hyperinsulin.

Ætiology and Physiology.—Tumours of the Islands of Langerhan are very rare and may be either innocent or malignant. They produce excess of insulin and therefore cause hypoglycæmia. The onset is insidious and the patients complain of hunger, weakness, sweating and shaky hands. These attacks usually occur some hours after a meal, and especially when the next meal is delayed. The symptoms are always relieved at once by sugar or a starchy meal. The attacks gradually become worse with much sweating and tremor; the patients may become very anxious or excited and resemble "drunk" people. Attacks of severe abdominal pain may occur and exploratory laparotomies have been performed without benefit. They also have epileptiform convulsions and become unconscious so that a diagnosis of epilepsy or cerebral tumour may be made.

Diagnosis.—This is often made by the patient who discovers that the symptoms are relieved by the taking of sugar, but if not, the correct diagnosis may be delayed for a long time. If the patient is unconscious the blood sugar will be 25 mg. per 100 c.c. or less which clinches the diagnosis. If, however, the symptoms suggest the diagnosis, a sugar tolerance test should be performed. The fasting value of the blood sugar is always 50 mg. or less per 100 c.c. and after 30 and 60 minutes may not rise above 120 mg. and soon returns to 50 mg. and may gradually decrease below this figure; some 4 or 6 hours after the sugar the patient may then develop the typical symptoms and become unconscious with a very low blood sugar.

A blood sugar curve of this type is diagnostic of a tumour, but many patients have the mild symptoms of hypoglycæmia without any tumour being present. The sugar tolerance curve in these cases is quite different in character. The fasting value is usually higher than 70 mg. per 100 c.c. and the blood sugar may rise in 30 or 60 minutes to over 200 mg. per 100 c.c. and then fall very slowly. Mild symptoms may develop when the blood sugar is still over 100 mg. and the blood sugar does not fall below 70 mg. per 100 c.c. Glycosuria may occur during the first one or two hours owing to the blood sugar being above the threshold of the kidney for sugar. This type of hypoglycæmia is not due to a tumour of the Island, but is believed to be due to some disorder of the liver. Functional Hypoglycæmia.

Treatment.—The mild symptoms are readily relieved by sugar or starchy food, but if a tumour is present and growing in size the amount of sugar necessary to relieve the symptoms increases and must be given many times in the day and the patient must be awakened once or twice at night in order to prevent attacks. When the diagnosis is well established the tumour should be removed. The operation may be very easy as the tumour may be readily felt when the pancreas is exposed, but it may be behind the head or even outside the pancreas. If a tumour cannot be found in a proven case the whole pancreas should be removed in either one or two stages. When the tumour is found or the whole pancreas removed the improvement in the condition is dramatic, though if the tumour is an adenocarcinoma and has disseminated to the liver, etc., the symptoms may recur.

If the sugar tolerance curve negatives the diagnosis of a tumour the diet

should be changed to one containing a high protein content. 100-120 g in the day and the carbohydrate reduced to 100 g. or less. This may be sufficient to relieve the symptoms. If not injections of insulin 10 or even 20 units three times a day which should cause hypoglycæmia may completely relieve the attacks and can later on be gradually reduced and then given up. It is most important not to operate on this type of case.

GOUT

A disease in which there is a disturbance of the purin metabolism and an increase of uric acid in the blood. The clinical sign is an attack of acute arthritis with a deposition of sodium biurate in and about the joints.

Ætiology.—*Predisposing causes.*—Gout is much commoner among certain races, e.g. the English and German. It is very uncommon among native races. It does not follow, however, that this is a racial peculiarity. It is much commoner in temperate than in tropical climates, but it is unlikely that the climate plays any part in the causation of the disease. The evidence in favour of gout being an hereditary disease is very strong, as a history of a gouty ancestry can be obtained in 50 to 80 per cent. of the cases. A history of gout in the family was obtained in 75 per cent. of well-to-do patients and in 50 per cent. of hospital patients (A. B. Garrod). This evidence suggests that the disease is chiefly hereditary but may be acquired. It is not the disease which is inherited, but only the predisposition to it, and the disease may lie latent until it is evoked by other causes (Llewellyn). It is a disease of middle life—between the ages of 35 and 50—but it may occur much younger, even in schoolboys who have a strong hereditary taint. The malady is very much more common in men than in women. Women form only 5 to 20 per cent. of the patients in most statistical tables.

Exciting causes.—Food plays a part in the causation of the disease, but it is rather the quality than the quantity which matters. Meat and the purin bodies in tea, etc., probably have little effect, but sweetbreads, liver, kidneys, fish roes, tripe may be actively harmful. Spirits have little effect, and gout is almost unknown in Scotland. Beer is much more potent and is probably partly responsible for the prevalence of gout in England and Germany. The strong wines like port and sherry, and the red wines such as Burgundy and claret, are also probably responsible for much gout among the well-to-do classes, and champagne has a bad reputation. The light white wines like Graves and hock and cider are less evil. Gout was formerly very common among lead workers in England, and it seems to be a concomitant cause. Trauma plays a great part in the causation of the acute attack. The big toe may be affected so frequently because of the pressure of the boot. An injured joint may be the seat of the first attack of gout. Syringing the ear of a gouty patient for cerumen was followed by an acute attack in the external auditory meatus (A. E. Garrod). Local sources of infection are very common among gouty patients, e.g. septic gums and tonsils. These used to be called gouty manifestations, but Llewellyn thinks that they may be responsible for causing the attack of gout.

Physiology and Pathology.—The fact that sodium biurate was deposited in and around the joints suggested that uric acid played an essential part

in the causation of gout. After A. B. Garrod had demonstrated by means of his thread test that the blood of gouty patients contained uric acid in abnormal quantities the hypothesis seemed to be proved. The problem is, however, not so simple as was thought at first.

The uric acid which is excreted in the urine of healthy people on an ordinary mixed diet comes from two sources, exogenous and endogenous. When all the exogenous sources of uric acid, *e.g.* meat, fish, sweetbread, tea and coffee, etc., are removed from the diet the output sinks to a level of 0.5 to 0.7 g. per day. The amount is fairly constant for each individual. If all proteins are removed from the diet, the endogenous uric acid output falls to a lower level than before (Folin). The removal of carbohydrates and a reduction of the caloric value of the diet also cause a decrease in the endogenous uric acid output to the lower level (Graham and Poulton). The endogenous uric acid output is believed to come from the breakdown of the cell nuclei of the body, *i.e.* wear-and-tear, but it can also be synthesised from histidin and arginin (Hopkins and Ackroyd). When the exogenous purins are eaten, or when uric acid is injected, there is an increase in the uric acid output, but the whole of the uric acid is not excreted in one day. If cinchophen is given at the same time, the excretion-rate of the uric acid is increased.

The blood always contains uric acid, and the limits of normal variation in health are 1 to 3 mg. per 100 c.c. The total uric acid in the blood of a man weighing 10 st. 3 lb. or 65 kilos would be 50 to 150 mg., assuming that the blood constitutes $\frac{1}{13}$ th of the body-weight, *i.e.* 5000 c.c.

In cases of gout there is usually a considerable increase in the amount of uric acid in the blood. Before an attack the blood may contain 4 to 6 mg. of uric acid per cent., though occasionally between the attacks there may be only a slight increase. The uric acid may also be increased in some people who have never had gout; as, in leukæmia, where there is a great destruction of leucocytes, and in cases of renal failure. The increase in the uric acid in the blood is, therefore, not pathognomonic of gout, although it is extremely suggestive of it.

In gout the output of uric acid varies widely. It may be quite small in amount, less than 0.20 g. per day, or it may be equal to that excreted by healthy people. Before the attack of gout it is usually very small in amount, but the paroxysm always causes a great increase in the output for a few days only. When purin bodies are eaten by a gouty patient, or if uric acid is injected, there is great delay in the excretion of uric acid. If cinchophen is given at the same time, the uric acid is excreted much more quickly. The diminution in the uric acid output may be due to an increased destruction in the body or to its retention by the kidneys. There is no evidence of increased destruction in the body, as the blood of a patient before an attack may contain 4 to 6 mg. of uric acid per 100 c.c. This suggests that the uric acid is retained by the kidneys. When cinchophen is given to a patient whose blood contains 4 to 5 mg. per 100 c.c. uric acid there is a great increase in the uric acid output and a decrease in the uric acid in the blood (Folin and Lyman). The "extra" uric acid excreted in 6 days (Fig. 12) was 1.9 g., while the blood uric acid decreased from 4.5 mg. to 2.9 mg. per cent. The "extra" uric acid must come from the uric acid in the body fluids, as the blood does not contain enough uric acid (Graham) (Fig. 13).

The evidence points to the view that although gout cannot exist in the absence of excess of uric acid in the blood yet uric acid is not the cause of gout.

The essential change is the deposition of uric acid as sodium biurate in the joints. The sodium biurate appears to be plastered over the surface of the cartilage, but on microscopical examination it is seen that there is a layer of cartilage over the deposit, which is always interstitial. The deposits may be quite small or enormous. In many cases the structure of the bones is destroyed and replaced by sodium biurate. The ligaments, tendon sheaths and bursæ are also infiltrated. The big toe joints may contain sodium biurate, although the patient has never had an acute attack

FIG. 13.—Figure showing the increase in the output of uric acid in the urine and the decrease in the uric acid in the blood after cinchophen (Graham)

of gout. The skin covering a tophaceous deposit may ulcerate and break down, and small masses of sodium biurate may be discharged (chalky gout).

Tophi.—Sodium biurate is also deposited in the cartilage of the ear, especially in the outer margin of the pinna. The tophi appear as white nodules, and uric acid crystals can be recovered from them, which also give the murexide test and a blue colour with Folin's phospho-tungstic reagent.

The kidneys.—An uratic deposit may occur in the pyramids. Norman Moore found it in 12 out of 80 cases. Well-marked changes of chronic interstitial nephritis are often found.

Symptoms.—The earliest sign of gout is sometimes the deposition of sodium biurate in the cartilage of the ear (tophus). This stage usually passes unnoticed, but is sometimes accompanied by an intolerable itching or tenderness.

Acute gout.—The first attack of "classical" gout usually occurs at

night. There may have been a few preliminary symptoms, such as dyspepsia, slight pain in the hands, and irritability of temper, but the patient goes to bed feeling well. "The patient suddenly wakes with pain, more or less intense, in the ball of one great toe, frequently accompanied with a slight shivering; the pain in the toe gradually increases and is attended with a sensation of burning, throbbing, together with great tension and stiffness; heat of skin and other symptoms of febrile disturbance usually follow the shivering, accompanied with a considerable degree of restlessness" (A. B. Garrod). The temperature is raised to 101° or 102° F., but after a few hours the patient begins to sweat and finally falls asleep. "In the morning the toe is swollen, the skin shiny, tense and dark red, and the whole joint is extremely painful" (A. B. Garrod). Usually the acute pain lessens in the daytime, but returns with great violence in the night hours. The temperature remains high and the temper of the patient is irascible in the extreme. The attack may last many days or pass away in two days. When the attack is ceasing "the inflamed joint becomes less intense and swollen, and pitting is readily produced on pressure" (A. B. Garrod). The attack may spread from the great toe to the other joints of the tarsus or to other joints of the body. The first joint of the big toe is most commonly affected. The ankles, knees and small joints of the hand and wrists are next in the order of frequency.

During the attack there may be a considerable degree of leucocytosis, 20,000 to 25,000, and all but 2000 to 3000 are polymorpho-nuclear cells as the lymphocytes and other cells are unaltered by gout. The uric acid output, which was low before, is greatly increased for a few days. Sodium biurate is deposited in the cartilage of the joint and head of the bone, but the swelling and stiffness may eventually disappear completely. The acute attack may be complicated by a severe gastro-intestinal disturbance which may be fatal. There may be other symptoms, such as dyspnoea, delirium and coma, but these are probably due to a coincident uræmia. Phlebitis of the veins of the limb may be a complication of an acute attack.

After the attack, whether as the result of illness or as a consequence of the simple living which the patient has endured, the general health of the patient is much improved. The attack usually follows in the spring and autumn. The second attack may follow at once, or may be delayed for many years.

Chronic gout.—After several attacks the joint does not recover completely. The deposits of urates occur in the ligament and capsule, as well as in the articular cartilages and bones. The joint, therefore, becomes swollen and irregular in its shape. The urate is especially deposited in the bursæ about the joints. In the advanced stages the skin over the uratic deposits breaks down and masses of chalky material are extruded, and the wounds heal with difficulty. The general health of the patient suffers after several attacks and does not recover completely. Dyspepsia is complained of, and the patient may show signs of high blood-pressure and arterial disease. The urine is increased in amount, and may contain albumin and casts.

Irregular gout.—Almost any symptom or physical sign which occurred in a person who was of a gouty disposition was formerly ascribed to gout. Cutaneous eruptions, such as eczema, gastro-intestinal disorders, cardiovascular symptoms and pericarditis, headache, migraine and neuralgia, were

FIG. 14—Line drawing from a radiograph, showing the changes which take place in the bones due to the deposition of sodium biurate.

all thought to be gouty. A gouty patient may develop any of these diseases, but the belief that there is a general type due to gout is now regarded as unfounded. The urine is usually acid, and on cooling often deposits uric acid crystals. This does not mean that there is an excess of uric acid in the urine, but that the urine is too acid to keep the uric acid in solution. On heating the urine the urates are re-dissolved. Gouty persons may suffer from calculi. Glycosuria occurs in some cases, but usually responds readily to treatment. Albuminuria and casts are present when the kidneys are also affected. Elderly persons often suffer from chronic bronchitis. Gout has been accused of rendering patients more disposed to iritis, retinitis and glaucoma. It is possible that iritis and retinitis have a gouty basis though they may arise independently.

Diagnosis.—The diagnosis in a case of classical gout, with recurring attacks of arthritis in the toe or tarsus, is easy, especially if the patient comes of a gouty stock or indulges in good food and drink. The presence of tophi is proof positive that the patient is a subject of gout. Tophi must be distinguished from Woolner's tip, fibroid nodules and sebaceous cysts, and in cases of doubt an examination should be made for the crystals of sodium biurate with the microscope, and for uric acid with the murexide test or Folin's phospho-tungstic reagent. The blood should be examined for uric acid in all cases of doubt, and if more than 3 mg. per cent. are found the case is probably one of gout; it may be normal in amount just after an acute attack. It must be remembered, however, that the uric acid in the blood is increased in cases of chronic interstitial nephritis. While it is certain that gout does not occur in the absence of an increase of uric acid in the blood, the presence of excess of uric acid in the blood does not exclude the presence of other diseases.

Classical gout is much less common than it was, and the modern tendency is to overlook the disease. In the severe cases of gout in which the joints are severely damaged, the X-ray appearances are very striking (Fig. 14). The negative shows dark areas where the sodium biurate is deposited in large amounts and replaces bone or cartilage, since sodium biurate is not opaque, like the calcium ion. In the less severe cases there may be—(1) lipping at the articular margins; (2) a localised atrophy of the bone; (3) a narrowing of the joint space. These changes occur in other kinds of arthritis and are in no way characteristic of gouty arthritis (Llewellyn).

Prognosis.—If a patient has once had an attack of gout he will always be liable to another attack, unless he alters his way of living. The frequency and severity of the attacks can be modified by treatment. The prospect of long life depend upon the state of the heart, arteries and kidneys.

Treatment.—*Dietetic.*—In perhaps no other disease have a greater number of dietetic fads been recommended. The total quantity of the food should be kept within reasonable limits, and civic dinners should be avoided. The meals should be simple but attractive. There is little difference between the different kinds of meat, except that for those who have dyspepsia chicken is more easily tolerated than beef and mutton. There is no need to deprive the patient of sugar, which is a common fad, or of starchy food, but they should be eaten in moderation. The same is true of fat. Some gouty persons are much too stout, and a reduction of weight is beneficial.

DISEASES OF METABOLISM

All protein foods contain purin, but their content varies widely (see table below). The foods which contain more than 100 mgs. per 100 g. should be avoided, as the uric acid which is formed from the breakdown of the purin is excreted more slowly by the gouty patient than by the healthy one.

THE PURIN CONTENT OF VARIOUS FOODS (R. A. McCANOE)

Material (All cooked)	Purin Nitrogen mgs. per 100 g. (3½ ozs.) of Edible Food
Brains	33
Mutton (general average)	63
Fish (" ")	65
Pork (" ")	69
Beef (" ")	81
Birds (" ")	94
Hearts	116
Cod roe (hard)	120
Livers and kidneys	140
Herring (no roes)	150
Smelts	168
Sprats	180
Sardines	234
Whitebait	323
Throatbreads, Sweetbreads, etc.	426
Herring roe (soft)	480

Attacks of gout have followed very quickly after eating sweetbreads and after the administration of purins for experimental purposes. The fruits and vegetables which contain an excess of oxalates, i.e. strawberries, rhubarb, spinach and asparagus, should be forbidden if oxaluria is present.

Heavy beers, strong wines like port and sherry, all red wines, and also champagne, should be forbidden for gouty patients. The white wines, like Graves and hock, may be allowed in moderation if especially desired. If drunk in moderate amount and well diluted, whisky is probably the least harmful beverage. Mineral waters may be of considerable benefit to gouty persons. Their mode of action is uncertain, but is probably due not so much to the ingredients of the waters as to the amount of water drunk, the simple and restricted diet, and the regular and supervised life which the patient leads at a spa. Hot baths and douches are of assistance in aiding the recovery of stiff joints. The waters of Buxton and Bath in England, Vichy, Aix-les-Bains and Contrexéville in France, Wildbad and Homburg in Germany, Carlsbad and Marienbad in Moravia, and Saratoga, Bedford and White Sulphur in America, are the best known.

Local.—During the acute attack the joint should be covered with cotton-wool, placed on a pillow, and the bedclothes raised by means of a cradle. Hot fomentations or cold lotio plumbi c. opio may be applied.

Internal.—The treatment should be started with a purgative, and calomel

is recommended. Colchicum is specific for the acute attacks. The pain is usually relieved quite quickly, and the redness of the skin and swelling of the joint subside. Fifteen to 30 minims of the tincture in an alkaline mixture should be administered every 4 hours. The drug may cause vomiting or purgation, and its action must be carefully watched. Its mode of action is quite unknown, and it is of no value in averting an attack. Cinchophen (Trade names : atophan, agotan, phenoquin, quinophan) is useless in relieving the pain of an acute attack, but it is most useful in averting attacks. It is given in tablet form, gr. 15 three times a day for 1, 2 or 3 days consecutively in each week and should never be given continuously. It increases the output of uric acid in the urine and decreases the amount of uric acid in the blood, and thus prevents the continuous accumulation of uric acid in the body. The drug may, however, produce unpleasant symptoms, such as urticaria, dyspepsia and jaundice. The complication of jaundice may be a very serious matter, for acute yellow atrophy of the liver may develop and death ensue. These toxic effects have usually, but not always, occurred : (1) when the drug has been given continuously, i.e. without an intermission of 4 to 5 days between the courses ; and (2) when its administration has been continued after minor symptoms of toxic action have appeared. The results of the treatment of undoubted cases of gout with cinchophen are so good that its toxic action is most unfortunate. It would seem that its use should be restricted to the treatment of gout, and only given in short courses each week and discontinued at the first indication of intolerance. Further, as soon as the acute joint condition has passed, the dosage should be reduced to 15 gr. twice a day, one day each week for 2 to 3 months. In a long-standing case, it should then be given once a month, or once in 3 months for an indefinite period. Aspirin and sodium salicylate have a similar action to cinchophen and may be used instead of it. Aspirin gr. 10 with glycine gr. 20, is given three times a day for one or two days each week in the chronic case, or more frequently if an attack is threatening ; it is not so efficacious as cinchophen, but is unlikely to cause any complications.

The general health of the patient must be attended to and all causes of sepsis should be removed. Radiant heat and massage are very useful for restoring the movements of a crippled joint.

OBESITY

Obesity is a condition in which there is an excessive amount of body fat.

Ætiology.—Certain races are more prone to become fat than others, *e.g.* the Dutch, South Germans, South Italians, Maltese, Hebrews, the natives of India and Ceylon, and some African races. A clear history of heredity was obtained by Fitcher in 60 per cent. of his cases. Obesity may develop at almost any age, but it is more likely to occur at certain ages : in babies, in children at puberty, in men after the age of 40, and in women during pregnancy or after the menopause. It is commoner among females than males.

Pathology.—The deposit of fat indicates that the caloric value of the diet is in excess of the individual's needs. This may be due to the large amount of food which is eaten, or to a small energy consumption in the body. Some fat people have a very large appetite and eat much

more than is necessary to satisfy their energy requirements. The amount of exercise which is taken has a great influence on the amount of fat which is deposited. Thus, a patient who is lying in bed will gain in weight on a diet which contains less caloric value than that which he eats when he is up and about. Although many cases of obesity are easily explained on the above grounds, there are many instances which cannot be explained so simply.

The investigations of the basal metabolism help us to understand many of these cases. The amount of oxygen which is burnt depends on the state of the patient. More combustion of oxygen takes place when the patient is taking exercise than when he is at rest, and when he has a meal than after a short fast. The metabolism of the resting, fasting individual is termed the basal metabolism. This is expressed in cubic centimetres of oxygen per minute per square metre of body surface. The basal metabolism (p. 431) is lower for adults than for children, and gradually decreases with each decade. It is lower for females than males. The basal metabolism can be altered by prolonged undernutrition and by the influence of the ductless glands. One of the results of underfeeding is a lowering of the basal metabolism, but the oxygen consumption of such a patient during exercise is unaltered. The action of the thyroid gland on the basal metabolism has been carefully studied, as there are two clinical conditions in which the thyroid plays an important part, namely, (1) in hypothyroidism, and (2) hyperthyroidism. In the first, the patients, among other symptoms, tend to increase in weight, and the basal metabolism in these cases is much lower than usual. In the second, one of the prominent complications is the rapid loss of weight which occurs, and the basal metabolism is much increased in these cases, and can be increased by giving thyroid extract and decreased by removal of large portions of the gland. When the basal metabolism is low, it is clear that the patient will tend to get fat, although he is eating less food than a patient whose basal metabolism is high. These experiments help us to understand many cases of obesity.

The action of the other ductless glands is not so well understood. When the posterior lobe of the pituitary gland is damaged by a tumour, considerable changes take place in the metabolism. The patients grow fat, and the fat is deposited in the characteristic feminine situations, i.e. the breasts and hips in male and female patients (Fröhlich's syndrome). When the anterior lobe is removed in dogs there is an increase in the weight of the animal (Cushing). Tumours of the adrenal cortex are associated with obesity and lesions of the hypothalamus may also be responsible.

The sex glands have a considerable influence on the metabolism. When the glands develop at puberty there may be an increase or decrease in the fatty deposits. The female lays down fat around the breasts and hips, and assumes the characteristic feminine form. Removal of the testicles, as in eunuchs, usually causes an increase in the body-weight. During a pregnancy women often grow stout long before they have to restrict their normal activities, while after the pregnancy is terminated, the patient may lose weight, and recover her figure. At the menopause many women tend to become stout and men usually get fat if castrated.

In obesity the fat is deposited in the subcutaneous tissues, the great omentum, mesentery, and around all the organs, such as the heart and kidneys.

Symptoms.—The presence of large deposits of fat limits the activities of the patients and destroys their good looks. Many of the patients feel well, but some complain of difficulty in moving about, because of their great bulk. Others complain of shortness of breath on the least exertion and may suffer from cardiac failure. Some of the patients are anæmic. Eczema may occur on those parts of the skin which touch each other. Diabetes mellitus occurs more frequently if patients are over weight.

Treatment.—*Dietetic.*—If the patient has only gained a little weight, moderate restriction of the carbohydrate and fat of the diet, together with an increase of exercise, may be sufficient. This is the basis of the well-known Banting cure. When the obesity is considerable, more drastic treatment is necessary if the patient really wishes to lose weight. The treatment may be started in two ways. (1) With a fast day, when the patient should stay in bed. Tea and coffee, with milk and sugar, and gravy soups may be taken in any quantity. The fast day will often cause an initial drop of 1 or 2 lb. in weight and also a reduction in the size of the patient's appetite. The fast day should be repeated once a week, and after a few times the patient need not stay in bed. (2) With a fruit day. A sufficient amount of fruit and vegetables is taken to provide 80 g. of carbohydrate (see Food-Tables, p. 451). The fruit day causes less discomfort than a fast day, partly because of the bulk of the food eaten and partly because the carbohydrate maintains the blood sugar at the normal level, and so prevents the formation of acetone bodies. The patient will be more willing to repeat a fruit day than a fast day once or twice a week.

The three components of the diet, *i.e.* fat, carbohydrate, and protein, should be reduced in different proportions. The fat should be reduced as much as possible, because it has a very high caloric value and the patient has already an excess of fat in his body. Butter, cream, the fat of meat, and especially that of ham and bacon, should be avoided. Chicken is better than mutton or beef, as it contains less fat, while white fish contains no fat. The carbohydrates should be considerably reduced, but this must be done cautiously; for many patients are made miserable, complaining of lassitude and extreme hunger if less than 100 g. of carbohydrate are given. This is probably due to the blood sugar being too low, since these symptoms occur as a result of an overdose of insulin (p. 440). The protein should be reduced least of all, for its combustion causes an increase in the metabolism of the body—the specific dynamic action of proteins. The total caloric value of the diet may have to be reduced to 1500 calories (carbohydrate (C), 150 g.; protein (P), 70 g.; fat (F), 64 g.); 1000 calories (C, 100 g.; P, 70 g.; F, 32 g.); 500 calories (C, 60 g.; P, 40 g.; F, 10 g.) (see Table of Food Values) before the patient begins to lose weight. The protein should be given in two meals only, or if very small amounts are allowed, in one meal, since it is better to make two or one good meal rather than three poor meals. The other meals should consist of starchy foods, fruit vegetables, and salads. The weight should not be decreased too rapidly. When the fat in the diet is small in amount the patient will suffer from a lack of vitamins A and D. This should be given in the form of radiostoleum, or adexolin, min. 3 once daily. A decrease of 1 to 2 lb. a week and 7 to 8 lb. a month is sufficient. The treatment should be persevered with until the patient's weight is about the average for the height and age. The patient should be encouraged to take more

exercise, but this should stop short of inducing undue shortness of breath. Physical drill and massage are of considerable assistance in increasing the energy needs of the body. Care should be taken not to eat more than usual after exercise, for this will neutralise any good effects of the exercise. A daily tepid bath (60°-70° F.) for 30 minutes will often aid the loss of weight.

Thyroid has been used in the past rather indiscriminately, as it increases the basal metabolism. If the patient has a low metabolic rate (B.M.R.), it should be prescribed; but if the B.M.R. is already normal, it may cause harm. The usual dose is 1 to 2 gr. twice daily. A careful watch should be kept for the onset of tachycardia, tremor, sweating, and glycosuria. When the B.M.R. is raised, more insulin has to be provided, and an elderly patient with a low sugar tolerance may develop glycosuria and have the symptoms of diabetes mellitus as the result of the administration of thyroid.

LIPODYSTROPHIA PROGRESSIVA

This is a rare condition, in which the subcutaneous tissues of the upper part of the body lose their fat, while those of the lower half remain unchanged.

Ætiology.—Females are affected more often than males. The cause of the condition is quite unknown.

Symptoms.—The patient feels perfectly well, but complains that the appearance of the face has altered, having become much thinner. The arms and trunk may also be similarly affected. The condition starts in the face and gradually descends to the arms and trunk. The legs are usually unaffected. On examination, the skin can be picked up easily and it is obvious that there is no fat in the subcutaneous tissues. The malar bones are very prominent. The whole appearance of the patient suggests a severe wasting disease. The breast and mons veneris in females are usually unaffected.

Course.—The condition progresses slowly.

Diagnosis.—This is made by comparing the subcutaneous tissues of the upper half of the body with those of the lower. The presence of a severe wasting disease must of course be carefully excluded.

Treatment.—Nothing is known which has any effect on the condition. The patient should be assured that no serious disease is present.

THE LIPOMATOSES

Ætiology.—This is unknown, but changes both in the thyroid and pituitary have been described.

The main types of the disease are:

1. *Adoposis dolorosa* (*Dercum's Disease*).¹—This syndrome is much commoner in women than men, 7 to 1, and begins between the ages of 45-60. The onset is very gradual and insidious. There is an increase in the fat chiefly (1) on the shoulder girdle and upper arm and to a lesser extent on the forearm; (2) on the buttock thigh and to a lesser extent on the legs;

¹ Lyon, *Arch. Int. Med.*, vi., 1910, p. 28.

(3) on the abdomen and back, so that the fat may hang in folds. The hands and feet are unaffected. The skin is not adherent to the fat. The fatty deposits have a peculiar texture and has been described as like a bag of worms or caked breast (Dercum). These fatty deposits may be exquisitely tender or may be quite painless. In some cases pressure on the nerve trunks may cause pain. Great asthenia may be present. Mental changes may occur and vary from mild to severe psychic changes.

Diagnosis.—This is made by the distribution of the fat and the freedom of the hands and feet from excess fat, together with the complaint of pain in the fat areas.

Treatment.—This is very unsatisfactory. Thyroid gr. 2-4 once a day is worth a trial, but a careful watch must be kept for symptoms of intolerance like tachycardia, sweating, tremor and glycosuria. Extracts of the anterior lobe of the pituitary have been tried, but at the present time doubt is cast on the efficacy of any of the preparations given by mouth and none are available for subcutaneous injection. The general dietetic treatment for obesity should be instituted as soon as possible.

2. *Nodular circumscribed lipomatosis.*—The lipomata may be few in number or very numerous, symmetrical or asymmetrical, large or small. Most of them are painless, but some are very tender and painful. Asthenia and mental changes, such as occur in adiposis dolorosa, may be present.

3. *Diffuse symmetrical lipomatosis of the neck*—This condition occurs chiefly in males, and the tumour usually appears after the age of 20. The thyroid and pituitary glands showed pathological changes in two cases. The fatty tumour is diffuse and symmetrical. The common sites are beneath the chin, at the nape and base of the neck, and the pre- or post-auricular region, and occasionally on the trunk. The tumour bears no relation to the general obesity of the patient. It is usually complained of because of the disfigurement which is caused. Pain, asthenia and mental disturbances may be present.

4. *Neuropathic oedema, pseudo-oedema, pseudo-lipoma.*—Swelling of the limbs may occur in patients with hysterical affections. This resembles at first sight an oedematous swelling, but it does not pit on pressure. It is due to a deposition of fat in the subcutaneous tissues.

Treatment—This is very unsatisfactory. Thyroid gr. 1 t.d.s. has given the best results, but pituitary (posterior lobe) extract should be also given a trial. Aspirin may relieve the pain.

GEORGE GRAHAM.

SECTION VI

DEFICIENCY DISEASES

VITAMINS

A COMPLETE and balanced diet must contain a sufficiency of each of the vitamins as well as the correct amount and proportion of protein, fat, carbohydrate and mineral salts. Vitamins are present in only minute amounts in various foods and were simply described by the letters, A, B, C, D, etc. Nearly all have been isolated and synthesised by chemists, and they have been named according to their properties and functions. The list of vitamins is as follows :

Fat soluble.

A group	{	A = axerophthol	}	from carotene.
		A ₂		
D group	{	D = same as D ₂ .	}	
		D ₂ = calciferol from ergosterol.		
		D ₃ = from 7-dehydrocholesterol.		
		D ₄		
		D ₆		
		E = α-, β- and γ-tocopherol.		
K group	{	K ₁ = methyl phytyl naphthaquinone	}	
		K ₂ = methyl difarnesyl naphthaquinone.		
		K synthetic = 2 methyl naphthaquinone.		

Water soluble.

B group	{	B ₁	}	B ₁ = aneurin or thiamin (F).	
		B ₄		}	not yet identified.
		B ₅			
B ₃ complex	{	B ₂ (G)	}	B ₂ (G) = riboflavin.	
		B ₆		B ₆ = adermin or pyridoxin.	
		B ₇		B ₇ = nicotinic acid or amide, Niacin.	
		B ₉		B ₉ = mainly pantothenic acid.	
		Biotin (H).			
C group	{	C	}	C = ascorbic acid (cevitamic acid).	
		P		P from hesperidin.	

Avitaminosis.—Absence from the diet of any one of the major vitamins causes a definite deficiency disease : scurvy (lack of C), rickets (D), beri-beri (B₁), pellagra (B₃), xerophthalmia (A). In the British Isles these major deficiency diseases are rare ; the most common, rickets in children, now occurs in less than 5 per cent. Absence of any one of the minor vitamins, B₂, B₆, E, H, K, P, induces certain specific symptoms.

Hypovitaminosis.—More insidious and less obviously connected with the diet are various chronic conditions due to partial deficiency of one or more vitamins, probably for a period of years and perhaps not fully manifest till middle life.

The minimal and optimal intake for each vitamin is known with fair accuracy. There is individual variation, and certain conditions, e.g., preg-

nancy, infectious diseases, intestinal parasites, greatly increase the requirement. The application of scientific work to the feeding of the nation during the war years 1939-1944 largely accounts for its good health in this period.

VITAMIN A

The presence of an unknown substance in fats became obvious from the normal growth of rats on some fats, but not on others. Animal fats, except lard, and the fat of green leaves promoted growth, while vegetable fats extracted from seeds did not. The growth-promoting values of the fats were very different, the very high value of cod-liver oil being most striking. Green leaves were superior to butter. The vitamin A value of milk was low, and was derived from the green food of the animal. Green leaves, carrots, and other parts of plants contain carotene, formed in the plant at the same time as chlorophyll. Carotene has also growth-promoting properties, and is pro-vitamin A. Carotene was shown by Moore to be converted in the liver into vitamin A. Three varieties of carotene are distinguished, α , β , γ , of very similar formulæ. β -carotene yields two molecules of vitamin A; the others only one. Other carotenoid pigments in plants are also precursors of vitamin A. Under the most favourable conditions only 50 per cent. of carotene is changed into vitamin A; more usually 30-40 per cent. is converted. Vitamin A (as well as carotene) is stored in the liver; body fat stores very little. Storage of vitamin A is helped by fat and vitamin E in the diet. Normal human liver contains 200 international units per gram of wet tissue: at birth, however, the liver contains very little vitamin A. The livers of fresh-water fish contain vitamin A₂, a slightly different compound, and there are other precursors, such as kitol in whale liver oil.

On account of the numerous precursors in plants and different forms in which vitamin A (an alcohol) and carotene exist in animals, chemical methods of estimation of vitamin A values of foods are difficult. The estimation is made by feeding experiments with pure β -carotene as standard; 0.6 microgram (millionth of a gram, $\mu\text{g.}$) is one international unit. One gram of vitamin A from fish livers equals 3,000,000 int. units. The approximate values of some foods are: halibut-liver oil, 16,000,000; cod-liver oil, average 200,000; calf's liver, 46,000; ox liver, 16,000; spinach, 13,000; cream cheese, 4600; butter, 2600; egg yolk, 3000; cheddar cheese, 5500; milk, 2300 international units per 100 grams or $3\frac{1}{2}$ oz.

The daily requirements of adults are 3000 to 4000; of infants 2000 to 2500; of older children and nursing mothers 4000 to 6000 int. units.

In the absence of vitamin A from the diet, young animals cease to grow, and as soon as stores in the body are exhausted become very susceptible to bacterial infections entering through the mucous membranes. The function of the vitamin is to keep healthy the moist surfaces of the epithelia and prevent hyperplasia, metaplasia, and keratinisation. If the supply of vitamin A is insufficient the fur of animals and feathers of birds become dry and ruffled, and the first visible symptoms are a peculiar and characteristic eye disease similar to xerophthalmia which had been observed in children. The eye disease is a special instance of keratinisation. The only treatment is vitamin A in cod-liver oil or other fish-liver oil. Local treat-

ment is of no avail. Cases of xerophthalmia were described by Budd in 1842, recorded by the explorer Livingstone in Africa in 1857, and Bloch, 1917-1924, observed many cases in Copenhagen.

Diets low in vitamin A lead to respiratory infections and bronchopneumonia. Abscesses at the base of the tongue, suppurating glands, pus in the middle ear, septic nasal sinuses, and infections of the digestive and genito-urinary tracts are noticed in animals, and have been clinically observed in man. Urinary calculi are common in experimental rats. In India, where stone is prevalent, McCarrison found that foods with vitamin A counteracted their formation. Toad skin is another symptom of vitamin A deficiency.

The epithelium at the junction of the teeth and gums in dogs was shown by May Mellanby to become overgrown and infected with micro-organisms (pyorrhœa). Vitamin A is necessary for the formation of dentine and enamel.

Lack of vitamin A causes degenerative changes in the spinal cord and the medullary sheaths of the sciatic nerves, and to disturbance of the œstral cycles and failure of ovulation. In puppies E. Mellanby has described bony overgrowth and deformity at the base of the skull, causing destruction of the divisions of the auditory nerve with production of deafness.

Hemeralopia or night blindness (really nyctalopia) is due to lack of vitamin A, the mother substance of visual purple. The dark adaptation test is a handy method of examining individuals for their state of vitamin A nutrition. Harris and his colleagues made a special study of this test, in which the technique must be carefully controlled. Thirty per cent. of children in an elementary school were deficient in vitamin A, and 39 out of 40 became normal after treatment. All children in a home where vitamin A was abundantly supplied were normal. Estimation of vitamin A in the blood is a better method of determining the nutritional level. Earlier indication of vitamin A deficiency is xerosis conjunctivæ, detected by biomicroscopy (Kruze).

VITAMIN D

The early work of E. Mellanby on the prevention of rickets by fats showed that they were much the same as those containing vitamin A. The difference between vitamin A and the antirachitic substance was demonstrated by McCollum, who found that cod-liver oil, after acration at a high temperature, was still antirachitic but not anti-xerophthalmic. The antirachitic substance was stable to heat, and distinct from vitamin A. McCollum called the antirachitic substance vitamin D. The existence of two vitamins in fats was confirmed from experiments with spinach; spinach was strongly growth-promoting and anti-xerophthalmic, but failed to prevent rickets. Spinach and green leaves contain vitamin A, but not vitamin D. Butter contains vitamin A, and very little vitamin D. Cod-liver oil contains vitamins A and D in large amounts. The irregular distribution explained the varied behaviour of fats.

Mellanby later investigated the rickets-producing effect of cereals in the diet. It was counteracted by vitamin D. The addition of calcium salts was also compensatory. The rachitic substance in cereals is phytin. Phytin has no toxic action, but forms an insoluble calcium salt and so removes it from solution; it has also an inhibiting action on the assimilation of calcium and phosphorus. The phosphorus of phytin is not available. Soluble

phosphates are necessary in a low phosphorus diet. May Mellanby carried out parallel experiments on the teeth. Perfect teeth were produced with an ample supply of vitamin D in the diet. Decayed teeth were associated with too little vitamin D; and similarly, with cereals in the diet if the calcium, phosphorus, or vitamin D were too low.

The physiological action of vitamin D is to regulate the absorption of calcium and phosphate from the food in the intestine so as to maintain these elements at their proper and optimal level in the blood. In the diagnosis of rickets the estimation of calcium and of phosphate in the blood is of value. A better indication of incipient rickets, however, is the estimation of blood phosphatase, a high blood phosphatase being an early symptom of rickets.

The curative action of sunlight upon rickets was well known, and could not be explained by the existence of a vitamin. The demonstration by Huldshinski, in 1920, of the curative action of ultra-violet light from a mercury vapour lamp made possible the experimental study of the action of light. Hume and Smith, at the Lister Institute, made the first observations leading to the explanation. Rats were kept in cages with sawdust as bedding. Some cages were exposed to ultra-violet light and others not so. Rats in the exposed cages did not get rickets, while the others did. The rats were seen to eat the sawdust. Light had produced in the sawdust an active substance having the effect of vitamin D. Next, foods known to be rachitic were exposed to ultra-violet light; they became antirachitic. The substance so activated was located in the fat, and traced to cholesterol and finally to an impurity in the cholesterol, later identified as ergosterol. Pure ergosterol from yeast on exposure to ultra-violet light is converted into active vitamin D. The new vitamin was isolated and called calciferol, and lettered D₂. Vitamin D₂, or calciferol, is not identical with vitamin D in fish-liver oils. A sterol, 7-dehydrocholesterol, was made from cholesterol and activated by ultra-violet light into vitamin D₃, which is as active as vitamin D₂. The same substance has been isolated from fish-liver oils, so it seems that vitamin D₂ and D are identical. Both D₂ and D₃ are equally active in preventing or curing rickets in rats and man; in chicks, however, vitamin D₃ is more active. The production of an active vitamin D from a sterol by ultra-violet light depends upon the structure of the sterol. Many sterols have been examined, and several give active vitamins, D₄, D₅, etc. Many are present in various foods, and serve as precursors of vitamin D.

Two factors are needed in the prevention of rickets—the one ergosterol or other sterol and ultra-violet light. Foods may contain the sterol or the activated sterol. The latter prevents rickets. The former is activated directly in the food, or indirectly, after consumption, in the fat under the skin. As a preventive measure against rickets the irradiation of foods is not altogether practicable. The food may become unpalatable and vitamin A is destroyed. Irradiated yeast is sometimes given to cows to improve the vitamin D value of their milk. Since calciferol has become a cheap commercial substance the best way of improving the vitamin D content of foods is by its direct addition in suitable quantity, as is carried out with dried milk and with margarine. Calciferol is available for medical use in various forms. Overdosage with calciferol must be avoided. The effect of high doses produces a big rise of calcium and phosphate in the blood, leading to abnormal deposits of calcium phosphate in the vascular system,

spleen, kidneys, liver and lungs. The best method of securing vitamin D is in ordinary foodstuffs with the sterol which is activated later by sunlight.

The vitamin D content of foods is expressed in international units. The international unit of vitamin D is 1 mg. of olive oil containing 0.025 microgram of calciferol. One unit daily heals rickets in young rats in 8 days. Coward and Morgan have given the following figures per 100 grams: halibut-liver oil, average 257,000; cod-liver oil, 12,700; butter, average, 100 to 200; cream, 50; milk, 10 to 100; egg yolk, 150 to 500; canned salmon, 600 to 800 international units.

The daily requirement of vitamin D varies with the available sunlight, the amount of sterol in the food, and the amounts and proportions of calcium and phosphorus. The U.S.A. Children's Bureau recommends for infants and children, 500-600 int. units to be increased to 1500 units at end of the third month. A teaspoonful of standardised cod-liver oil gives 500 int. units. In an ordinary diet adults have 150 or more int. units. Pregnant and lactating mothers require at least double this amount.

VITAMIN E

The failure of rats to reproduce on a diet containing cod-liver oil (vitamins A and D) and yeast (vitamins B₁ and B₂), announced by Evans and Bishop in 1922 and corroborated many times, is due to the absence of another fat-soluble vitamin E. Rats do not need vitamin C. Vitamin E is found in the oil of lettuce and green leaves, and in the germ of whole cereals. Vitamin E has been isolated from wheat germ oil, identified and synthesised. Three varieties exist, known as α -, β - and γ -tocopherol; α -tocopherol is the most potent. Vitamin E resists oxidation, but is destroyed by contact with rancid fats or with iron salts. Vitamin E acts as antioxidant delaying rancidity in natural fats and oils. It protects vitamin A against oxidative loss in the tissues.

The failure of reproduction is "resorption gestation," i.e. death of the foetus in the uterus and its resorption into the maternal organism. Females recover after giving wheat germ oil, but in males the germ cells degenerate and sterility is permanent. Other effects of vitamin-E deficiency are degeneration in the kidneys, discoloration of the uterus, muscular dystrophy, and alimentary exudative diathesis. There is no confirmation of reported cures of miscarriage in women. Cases with aching limbs, fibrillar nodules on arms and legs near the joints with creatinuria were relieved by treatment with 100-200 mg. tocopherol for 8-30 weeks.

VITAMIN K

A deficiency disease characterised by subcutaneous and intramuscular hæmorrhages with delayed clotting of blood in chickens was described by Dam and Schonheyder, in 1934, and ascribed to lack of a fat-soluble thermostable vitamin K. The long clotting time is due to reduced prothrombin content of the blood. The prothrombin time test of Quick using human thromboplastin is used in diagnosis. Vitamin K is most abundant in hog's-liver fat, and green leaves. Two natural substances vitamins K₁ and K₂ have been isolated and identified as 2, 3-derivatives of 1, 4-naphthoquinone. Synthetic 2-methyl-1, 4-naphthoquinone has similar properties. Clinically,

injections of emulsions of vitamin K have produced a reduction in the clotting time of the blood of patients with obstructive jaundice, due mainly to defective absorption from absence of bile salts. Hæmorrhagic states in infancy have responded to treatment with the vitamin. It is stated that vitamin K deficiency is the cause of part of the mortality of the new-born infant, in which the plasma prothrombin sinks to a very low level. Prophylactic treatment of the mother with 20 μ g. prior to birth or of the new born is successful. Two μ g. daily are required for maintenance. Normally, the rise of prothrombin level occurs when mother's milk becomes abundant.

VITAMIN B₁

Eijkmann's observations (1897) that fowls on a diet of white rice suffered from a peculiar form of paralysis called *polyneuritis gallinarum*, very similar to the symptoms of beriberi in man, and the cure of both birds and man on being given whole rice or rice bran, were the foundation of investigations on deficiency diseases. Whole cereals, pulses, and nuts were also found to be preventive, whereas white cereals led to the disease. The idea that a disease resulting from the absence of some unknown substance from the food is due to Grijns (1901). The idea was strengthened by Fraser and Stanton's extraction of the preventive substance by means of alcohol, and Funk's isolation of an impure substance, vitamine, which cured polyneuritis in pigeons.

The occurrence of beriberi amongst our troops in the Dardanelles and Mesopotamia during the War of 1914-1918 stimulated further investigations. Numerous foods were tested for their anti-beriberi value by Cooper, and by Chick and Hume at the Lister Institute using the pigeon as test animal. Their data on the cure and prevention of polyneuritis in pigeons were so similar to those on the growth of rats on foods tested for water-soluble B that these two unknowns seemed identical, but there were some differences to cause doubt. Another difference was in the stability to heat. The anti-beriberi vitamin is destroyed by high temperatures, especially in presence of alkalis, but the water soluble growth vitamin is stable. The Vitamin Committee of the Medical Research Council adopted the view of two different vitamins. They called the anti-beriberi vitamin B₁, and the growth-promoting vitamin B₂. The irregularities in distribution were due to differences in amount: yeast contains both equally; wheat germ has more B₁ than B₂; egg white has B₂, but not B₁; and meat has more B₂ than B₁. The comparative vitamin B₁ values of most common foods were examined by Plimmer, Rosedale, Raymond, and Lowndes, but in the absence of a definite standard at that time the data were quoted in terms of dried yeast as 100. Their figures correspond in most cases with the figures by newer methods in terms of the international standard. Vitamin B₁ is most abundant in dried yeast, yeast extracts, germ of cereals, pulses and nuts, with very little in leaves and fruits. Liver, heart, kidneys, egg yolk and cod's hard roe contain appreciable quantities, but lean flesh and fish flesh very little.

Estimations of vitamin B₁ in foods were made by Baker and Wright by the bradycardia method of Harris and Birch. The rate of the heart-beat of rats on a diet deficient in vitamin B₁ falls from about 550 to 300, and is rapidly restored on giving food containing vitamin B₁. The vitamin B₁ value

of the food is estimated by determining the amount of the food which restores the heart-beat in comparison with a standard preparation made from rice bran or a standard quantity of pure vitamin B_1 . A purely chemical method, in which the vitamin B_1 is extracted and determined after oxidation to thiochrome was developed by Pyke (1910).

Vitamin B_1 was isolated from rice bran and yeast, and its chemistry fully established. The pure synthetical vitamin, called aneurin or thiamin, is available for medical use and other purposes. Aneurin hydrochloride was adopted in 1938 as standard of measurement. Three micrograms correspond with one international unit. The amounts of aneurin in some common foods in micrograms $\mu\text{g.}$ per 100 grams are: dried yeast, average 9000; yeast extract, marmite, average 6000; wheat germ, bemax, average 3900; whole wheat, average 900; whole wheat bread, 360; brown breads, 150 to 420; white bread, 30 to 60; oatmeal, 300 to 510; lentils, 630; haricots, 360 to 480; fresh peas, 90 to 120; canned peas, 360; walnut, hazelnut, 450 to 600; vegetables, 30 to 210; fruits, 30 to 120; potato, 90 to 120; lean meats, 90 to 150; pork, ham, lean, 660 to 960; fish, 90 to 120; milk, 70; cheese, 0 to 90; liver, kidney, 450 to 570; egg yolk, 420.

Aneurin is closely connected with the metabolism of carbohydrate. In the form of its pyrophosphoric ester it becomes co-carboxylase, which is concerned with the removal of pyruvic acid. In the absence, or with too little aneurin pyruvic acid accumulates in the blood, tissues and brain. The excess of pyruvic acid in the brain causes the head retraction, the symptom of polyneuritis, in birds, and is the cause of bradycardia. In man the heart beat increases in rate. The estimation of pyruvic acid in the blood is a possible means of detecting and confirming beriberi.

Aneurin is excreted in the urine, in which it is estimated by oxidising to thiochrome, and extracting with butyl alcohol. Thiochrome shows a marked fluorescence in ultra-violet light according to quantity. Harris suggested the estimation of aneurin in urine to ascertain the level of nutrition of vitamin B_1 . The resting level of the subject is determined and a test dose of 1050 $\mu\text{g.}$ is given. In normals about 25 per cent. is immediately excreted as estimated 3 hours later. If less is excreted, the body is not saturated and the subject is on too low a level. The normal excretion varies according to diet from 50 to 170 $\mu\text{g.}$ in 24 hours; 90 $\mu\text{g.}$ is subnormal. On the reputed daily requirement of 900 $\mu\text{g.}$ the output is 137 to 233 $\mu\text{g.}$ On diets deficient in aneurin the output is 50 to 80 $\mu\text{g.}$, in cases of beriberi almost 0. Women show lower values during and after pregnancy.

The requirement of vitamin B_1 by man depends on body weight and energy metabolism. The amounts of vitamin B_1 in diets leading to beriberi were calculated by Baker and Wright to be 450 to 750 $\mu\text{g.}$: a 10-stone man consuming 3000 calories requires 900 $\mu\text{g.}$ daily to protect from beriberi; and a 14-stone man, 1125 $\mu\text{g.}$ Other authors estimate a daily requirement of 900 to 2700 $\mu\text{g.}$ The typical diet of white bread, butter, meat, sugar, and vegetables contains 600 to 1050 $\mu\text{g.}$, and in the case of the poorer classes usually the smaller amounts. A large proportion of the population is consequently on a borderline diet. The effect of borderline diets, i.e. hypovitaminosis, can be judged from the numerous experiments on birds and rats. With very little, the animals soon die with typical symptoms; with larger but still insufficient amounts, life is longer; with still more, the

animals live longer and die without showing the typical symptoms. Post-mortem examination shows enlarged heart, and intestines full of undigested food. McCarrison found these symptoms in the early stages of beriberi. The chronic enlarged heart and dropsical tissues were considered to be due to too little vitamin B₁. M. J. Rowlands studied the effects of too little vitamin B₁ on rats. He observed distension of the stomach and visceroptosis, and a slower evacuation of the bowels. Resistance to infection was weakened, and bacteria entered the body through the degenerated mucous membranes of the intestinal walls and infected other parts of the body. Drummond, Baker, and Wright (1938), in continuation of Rowlands' work, found that rats had a shorter duration of life, smaller litters, and a greater incidence of gastrointestinal lesions, especially ulcerations. Constipation, ulcers and cardiac troubles may thus in many cases be attributed to diets low in vitamin B₁.

VITAMIN B₂ COMPLEX

Several factors, B₂, B₆, B₇ with B₃ mainly pantothenic acid and H or biotin compose vitamin B₂ complex. The main medical interest is in B₇ or nicotinic acid amide or niacin which cures the chief symptoms of pellagra, and B₂ riboflavin, which cures angular stomatitis. B₆ pyridoxin or adermin is also required. Biotin is connected with so-called egg-white injury.

Generally, but not invariably, associated with a maize diet, pellagra occurs in parts of S.E. Europe, Egypt, and in southern districts of U.S.A. It was first described by Pedro Casals in 1707 under the name of *mal de la rosa*, and attributed by him to a poor diet. Goldberger in U.S.A. eliminated the disease in parts of U.S.A. with an increase of animal foodstuffs. Hence pellagra was attributed to lack of animal protein, or more specifically to absence of one or more amino acids not present in the proteins of maize. Experimental work did not support this idea. As dried yeast, beef, liver, salmon were highly curative but not casein, Goldberger concluded that there was a special pellagra preventing or PP factor. Its distribution in foods was so similar to that of water soluble B, or vitamin B₂, that he thought the two were identical, especially as rats on a synthetic diet containing a preparation of B₁ suffered from a dermatitis seemingly analogous to the dermatitis of pellagra. Lactoflavin, or more correctly riboflavin, was next isolated from egg white, milk and liver. It cured the rat dermatitis. Pure synthetical riboflavin, however, did not have the same result, and so it was assumed that an impurity, B₆, in the isolated riboflavin was the curative vitamin. Preparations of vitamin B₆, free from riboflavin, cured the dermatitis, but the animals failed to grow. Growth was restored with riboflavin. For rats the two vitamins are thus essential. Rats on a pellagra producing diet of maize and other cereals do not experience the dermatitis, as the cereals contain vitamin B₆. Vitamin B₆ is not the PP factor, and rat dermatitis is not analogous to pellagrous lesions in man.

It was known that dogs on a pellagra-producing diet suffered from sore mouth and tongue—"black tongue"—and were cured by diets with yeast, beef, liver, etc. One of the best curative materials of both black tongue and pellagra is liver extract. Elvehjem (1937) isolated from liver extract a substance resembling nicotinic acid. On testing pure nicotinic acid on dogs with black tongue, they were cured. Four cases of pellagra were treated

by Fonte *et al.*, and were cured, and later eleven cases were cured by Spies *et al* with intravenous injections of 30 to 100 mg. daily. Doses of 50 to 1000 mg. have been given to man without harm, but large doses give a sensation of heat with flushing of the face, chest and back and tingling of the skin. Martin, Chick *et al.* found that pigs on a pellagra-producing diet suffered from lesions similar to pellagrous lesions in man, and again nicotinic acid was curative. Rats differ from man, dog, pig and monkey in not requiring nicotinic acid, but all need riboflavin and adermin. In man not all the symptoms of pellagra are cured by nicotinic acid. The absence of riboflavin leads to scaliness and inflammation of the lips, and cracks at the corners of the mouth—"angular stomatitis." Chick, Macrae and Worden have discovered that rats on a prolonged deficiency of adermin suffer from epileptic fits, also previously observed in pigs. For the prevention of pellagra nicotinic acid, riboflavin and adermin are essential, though the significance of adermin is not clear.

Nicotinamide is a constituent of the dinucleotide co-enzyme concerned in the transfer of hydrogen in tissue respiration and of phosphorus in carbohydrate metabolism. Riboflavin forms the prosthetic group of Warburg's "yellow enzyme" of tissue respiration.

Nicotinic acid is estimated in foods by a colorimetric method improved by Harris and Raymond. Many analyses have been made by Kodicek. Liver has 17-20, ox muscle 4.3, sheep heart 6.0, egg yolk 1.0, milk 0.8, salmon 8.4, other fish 3-4, whole wheat 3.3, white flour 0.5-1.2, maize meal 1.0 to 1.8, potato 2.0, cabbage 0.3, marmite 64, "Eli Lilly liver extract 343" 109.0 mg. per 100 grams. The daily requirement is 12 mg. In U.S.A. a higher requirement of 15 to 23 mg. is considered necessary.

The same method of estimating nicotinic acid is applicable to urine and is used to determine the level of nutrition of this vitamin. The average excretion is 4 to 5 mg. a day. It is higher on diets with more nicotinic acid, such as yeast extract, and the output varies with the intake. In animals with a deficiency of nicotinic acid the output sinks almost to 0.

Riboflavin can be estimated by several methods. Yeast has 2-4, liver 2-4, kidney 2-4, meat 0.1 to 0.4, whole wheat 0.08, white flour 0.01 mg. per 100 grams. The requirement is to 2-4 mg. daily.

Biotin.—Dermatitis is produced in rats on synthetic diets with excess of egg white. It is cured by another vitamin of the B₂ complex called H (Gyorgyi, 1931). Vitamin H has been identified with biotin, known as a growth factor for yeast and bacteria. Egg-white injury is due to combination with avidin, a protein-like substance in egg white thus inhibiting the action of biotin. The combination is decomposed by steaming.

Pantothenic acid deficiency leads in rats to sealy dermatosis and alopecia. Its significance for man is not known.

VITAMIN C

In the Middle Ages it was recognised that fresh fruits and vegetables cured and also prevented scurvy, that dried fruits and vegetables had no effect, and that among fruits the orange and lemon were the best anti-scorbutics. A daily ration of not less than 1 oz. of lemon juice was used to prevent scurvy in the Navy; this quantity is man's minimal daily requirement.

Holst and Frölich's discovery that the guinea-pig on a diet without fresh fruit or vegetable suffered from scurvy made it possible to compare the antiscorbutic values of fruits and vegetables. These tests, first made by Chick and Hume in 1914-1918 for Army use, were extended to ascertain the effect of cooking. Fruits and vegetables vary considerably in antiscorbutic value. Orange, lemon, tomato, swede and cabbage have a high value; grapes, beetroot, and turnip a low one. Orange or swede juice was given instead of grape juice to infants to prevent infantile scurvy.

Cooking is destructive of vitamin C; rapid cooking being less harmful than long slow cooking. The heating of vegetables a second time destroys the vitamin. Vitamin C is very sensitive to heat in the presence of air. Further study on the effect of cooking was made by Olliver (1936-1941). About 50 per cent. of vitamin C passes into the water, about 20 per cent. is oxidised by ascorbic acid oxidase. This must be destroyed by throwing the shredded vegetable into boiling water (blanching). By this process there is little or no destruction of vitamin C in the canning of fruits and vegetables blanched and cooked in the absence of air. Jams and marmalade produced by long boiling in air do not contain vitamin C. Condensed and dried milk made by spray processes in which air is excluded retain their vitamin C value. Milk is low in vitamin C. Orange juice can be similarly concentrated and combined with dried milk. A most important source of vitamin C is sprouted peas, beans and grains of wheat or oats. Sprouted seeds are very valuable when fresh fruits and vegetables are scarce, and on long expeditions far from a base, though in these cases synthetical ascorbic acid is now taken.

Vitamin C was isolated from lemon juice by Waugh and King, and identified with a hexuronic acid obtained from suprarenal gland by Szent-Gyorgyi. Its chemistry is established, and the synthetical product is known as ascorbic acid or cevitamic acid.

Ascorbic acid is a reducing agent, and decolorises 2, 6-dichlorophenol-indophenol. This reaction was employed by Tillmanns to distinguish lemon and fresh fruit juices from artificial and boiled juices. This reducing property has become (under properly controlled conditions) the standard method of estimating ascorbic acid in fruits and vegetables. The amounts of ascorbic acid in mg. per 100 grams in some common fruits and vegetables are: black currants, 230; rose-hips, 520; orange and lemon juice, 50-60; gooseberries, red and white currants, 40-46; raspberries and tomatoes, 24; blackberries, 14; apples and bananas, 10-12; pears and plums, 1-3; grapes, 3. Parsley 176; kale, 145; sprouts, 112; cabbage, 90; cauliflower, 70; spinach, 65; swede, 40; lettuce, 20; potato, new, 20; old, 8; carrot, 6; milk, 2; human milk, 6; calf's liver, 33. Special syrups are made from black currants and rose-hips for feeding infants and children. Many of the body tissues contain considerable quantities of ascorbic acid, especially the suprarenal, intestinal mucosa, liver and eye lens. In scurvy in guinea pigs these organs have little or even none.

Vitamin C or ascorbic acid is excreted in the urine, and is estimated in acid solution by the reduction of 2, 6-dichlorophenolindophenol. The daily excretion varies from 15 to 30 (mean 20) mg. on a diet with plenty of fruit and vegetable, and from 5 to 11 mg. on diets with little antiscorbutic food. Harris and Ray devised the saturation test for assessing the level of nutrition of the individual. The test consists in feeding a large dose, 700 mg. or more, of

ascorbic acid as such or as orange juice and ascertaining if the output rises above that previous to the dose. If there is no rise, the body is unsaturated, but if 50 per cent. of the dose is excreted in 24 hours the body is saturated. A considerable number of people so tested were unsaturated. A simpler but less reliable test which serves as a guide is Gothlin's capillary resistance test. A pressure band is applied above the elbow. Bending the elbow produces increased pressure, and minute hæmorrhages appear if the capillaries are weak. Many children tested in Sweden had a low antiscorbutic intake, and improved on being given more. Ascorbic acid can also be estimated in blood. Blood plasma with not less than 0.4 mg. in 100 ml. is normal, on saturation the content is above 0.8 mg.

Man's minimal requirement of ascorbic acid to prevent scurvy is 1 oz. of lemon juice, or 20 mg. ascorbic acid. Höjer found that the teeth of guinea pigs rapidly degenerated with too little vitamin C, and that at least twice the minimal quantity was needed for prevention. Man would thus require 40 mg. Saturation tests have shown that 60 to 70 mg. are daily required. Babies are said to require 10 mg. daily. It is easier to give the figures as 1 mg. per kilo for man and woman; and 2 mg. per kilo for babies, pregnant and nursing mothers, and preferably also for older children.

A marked drop in the urinary excretion of ascorbic acid is observed at times of influenza or feverish cold. Patients with acute rheumatism, or tuberculosis, or osteomyelitis, or rheumatoid arthritis excrete less than non-infected control subjects. Such patients are in a state of lower saturation. In infections there is increased use or destruction of ascorbic acid in the body. There is no connection between ascorbic acid and antitoxin formation. The special action of ascorbic acid is, according to Wolbach, the production and maintenance of intercellular material, cementing the individual cells into a tissue. This explains the weakness of the blood vessels allowing hæmorrhages, and the lack of tone in skeletal muscles. The general disintegration of the tissues begins before the appearance of pain and the acute symptoms of scurvy.

VITAMIN P

The fragility and permeability of the capillary walls to plasma proteins is said to be due to a separate vitamin P, present with vitamin C in fruits. Scarborough described decrease of capillary fragility in certain clinical conditions by citrin, a product of orange juice. Ascorbic acid had no effect. Citrin contains the glucoside hesperidin from which vitamin P is derived. Further evidence is required.

R. H. A. PLIMMER.

SCURVY (SCORBUTUS)

Scurvy is a "deficiency" disease and is caused by the lack of vitamin C (ascorbic acid) in the diet. It consists in a general disorder of nutrition, characterised by debility, anæmia, sponginess and ulceration of the gums, and purpura and hæmorrhages into the subcutaneous tissues and failure of wounds to heal.

Ætiology.—The production of scurvy in guinea pigs by Holst and Fröhlich in 1907 gave the final proof that the disease is due to a lack of vitamin C—ascorbic acid (see Vitamins, p. 479). A complete lack of the vitamin does not produce any symptoms in man for four months, when debility appears, followed in the fifth month by hyperkeratosis of the hair follicles and by failure of an operation incision to heal in the six month. The other changes appear soon after this time. Scurvy occurs in young children who have been fed on dried milk, and also among adults who take freak diets or among old men and women who live alone—Batchelor's scurvy.

Pathology.—The pathological changes are: (1) An increased permeability of the capillaries to the red cells. This is responsible for hæmorrhages into the skin, subcutaneous tissues, under the periosteum, into the joints, and sometimes into the pleura and pericardium. (2) An interference with the normal growth of the erythrocytes. This produces an anæmia, which is usually orthochromic and normocytic, but may be microcytic or macrocytic. (3) A change in the bone, the result of unorganised provisional bone, which occupies a wide area at the growing ends of the bones. This bone is very friable. (4) In the normal process of healing precollagen is formed, which stains black with silver nitrate. This should be converted into collagen, which does not stain with silver nitrate after about a week. In scurvy and the sub-scurvy state collagen is not formed at the proper time, with the result that the scar is poorly united and may burst open easily and so cause peritonitis after abdominal operations, or herniæ. The adrenal may not contain any ascorbic acid under these conditions. The ascorbic acid in the plasma varies between 0.6 and 1.85 mg. per 100 c.c. in health, but none may be detected even when the patient shows few signs of ill-health. The amount of ascorbic acid excreted in the urine varies from 10 mg. to 50 mg. or more according to the amount of ascorbic acid taken; and the amount which is considered necessary for health is 25 mg. a day, though 50 mg. a day is necessary for complete saturation. A convenient method of testing the degree of unsaturation of the patient is to give 70 mg. of ascorbic acid per lb. of body weight at 10 a.m. The urine is collected from 1 p.m. to 3.15 p.m. If the patient takes over 50 mg. a day, 50 mg. will be excreted in the $2\frac{1}{4}$ hours period on the first day; if he takes 40 mg. a day, 50 mg. will be excreted on the second day; if 25 mg. a day is taken, 50 mg. will be excreted on the third day. The subject may show little sign of disease even if the standard excretion of 50 mg. is not reached until the fourth or fifth day. Patients with definite scurvy may take seven or eight days before the standard excretion is reached.

Symptoms.—Scurvy is a disease of insidious onset. The earliest symptoms are weakness and lassitude, dizziness on standing up. Hyperkeratosis of the hair follicles appears first on the back of the thighs and later involves those on the abdomen and calves. Some of the follicles are blocked by a yellow plug of keratin which projects very slightly. The hair is unable to escape and may show as a ring through the keratin in the early cases, before the plug gets too thick and obscures the hair. The gums begin to swell if teeth are present and may bleed easily, especially if the gums were unhealthy. The patient up till now may show no signs of ill-health apart from the lassitude, but now begins to look ill and the face becomes sallow and drawn. Later, the gums may swell so much that they cover the teeth

and bleed very easily—spongy gums. The teeth then get loose and may fall out. Another fairly early sign is the appearance of purpuric spots around the hair follicles, chiefly on the lower limbs. These are followed later on by hæmorrhages into the subcutaneous tissues, chiefly of the lower limbs, which may be very extensive and accompanied by œdema. The part affected by them is brawny, tender, and pits on pressure, the indentation persisting longer than it does in ordinary œdema. The skin over them is red, shiny and hot. Such effusions are common, also, in the popliteal space and in the bend of the elbow, as well as in the loose tissue around the malleoli, and beneath the muscles of the jaw. In these situations they form indurated swellings which fill up the natural hollows of the part, and greatly interfere with the movements of the adjacent joint. Where such effusions occur over the shins they are apt to be mistaken for syphilitic nodes. In some cases the skin may break easily, giving rise to ulcers which spread and show no inclination to heal. Hæmorrhages may occur into the knee, ankle or elbow joints and also into the muscles, causing hard tumours which may be adherent to the skin. In young children hæmorrhages may occur underneath the periosteum or into the epiphyseal area of the bone. This causes very great pain and the limb may appear to be paralysed. The child cries whenever it thinks it is going to be touched. Hæmaturia may occur to a mild degree and red cells can usually be found in the urine. Epistaxis may occur together with mæna, but hæmoptysis and hæmatemesis are rare. Bleeding into the pleura and pericardium may occur and also under the conjunctiva where it may be sufficiently extensive as to raise the ocular layer leaving the cornea at the bottom of a pit surrounded by swollen and red conjunctiva. As the disease progresses anæmia becomes a marked feature, though its degree has no constant relation to the extent of the ecchymosis. The hæmoglobin may be as low as 30 per cent. and the anæmia may be normocytic, microcytic or macrocytic and in the last case the condition may be mistaken for pernicious anæmia. Poikilocytosis and anisocytosis are common, but nucleated cells are rare. A leucopenia may be present, or there may be a moderate increase of the leucocytes. The number of platelets is not markedly decreased and the bleeding time is not prolonged. The coagulation time is normal. Pressure produced by a tourniquet at the pressure of 70 mm. Hg per 2 minutes may cause the appearance of purpuric spots. This was regarded as pathognomonic of scurvy, but is not always present. It may be due to lack of vitamin P, but this is not quite certain. When the patient is very ill a pyrexia of 101° F. or so may be present.

Alimentary symptoms may be absent. Appetite is not necessarily impaired; but dyspepsia may be present, as the result of the dietetic conditions which produce the disease. Constipation is the rule; but the conditions in which scurvy develops often favour the production of a diarrhoea and the stools may contain blood. Death used to occur suddenly in the severe cases.

Complications.—Signs of deficiency of other vitamins may be present.

Diagnosis.—If all the characteristic symptoms are present, and if the disease arises simultaneously in a number of subjects in circumstances known to favour its development, the diagnosis is easy. The difficulty occurs when sporadic cases are met and when the disease is not thought of. The diagnosis can be established by the absence of ascorbic acid in the plasma

and finding that the standard excretion of 50 mg. in the 2½ hours period three hours after the test dose of 70 mg. per lb. body weight is not reached until the seventh or eighth day, and by this time the patient will be well on the way to recovery. The mild cases may be mistaken for thrombocytopenic purpura, but the prolongation of the bleeding time and the diminished number of platelets should establish the diagnosis, if that disease is present. Further, in this disease the spleen is usually enlarged, the gums are not affected and the hæmorrhages into the subcutaneous tissues and joints are much less marked. The blood count should also exclude the leukæmias. The purpura due to infective endocarditis should be diagnosed on general grounds. Mercurial cachexia, which in many points closely simulates scurvy, is now but rarely seen, and an inquiry into the history will usually lead to a correct conclusion.

Prognosis.—In the mild cases this is good and the patients recover very quickly. Delayed recovery will occur when the hæmorrhages into the muscles and joints have been extensive, though ulcers and wounds heal readily. Coincident lung lesions and severe diarrhœa render the prognosis more serious, while sudden death may occur in very severe cases.

Treatment.—**PROPHYLAXIS** consists of a diet containing from 25–50 mg. of ascorbic acid (500–1000 international units), for this will prevent scurvy. (For details see p. 478.)

If the disease develops, a sufficiency of ascorbic acid should be administered at once. This can be given either as pure ascorbic acid, or in the form of the juice of a lemon, orange, or of grapefruit, or blackcurrants, all of which are rich in ascorbic acid. The patient will recover most quickly if 1000 mg. of pure ascorbic acid is prescribed daily for 3 to 5 days. After this, at least 100 mg. of ascorbic acid should be given in the form of orange juice until complete recovery has occurred. It is usually unnecessary to administer iron, since the anæmia recovers rapidly, but it is advisable to prescribe an adequate amount of the other vitamins, because the patient may also be suffering from a lack of these. Local treatment for the gums is advisable, the teeth should be scaled, and the gums sponged with hydrogen peroxide.

THE SUB-SCURVY STATE

Recent work has shown that many people are in what is termed the sub-scurvy state as the result of diets containing very little ascorbic acid. The symptoms are latent until an individual is wounded or operated on. Then the wounds heal very slowly and the operation wounds are apt to break open. Again, ulcers are liable to bleed. In such cases the diet should always be considered, and if found to be unsatisfactory, 2000–3000 mg. of ascorbic acid should be given. In cases of pyloric stenosis 300 mg. should be administered intravenously for 3 days prior to operation, and the usual dose immediately after it.

GEORGE GRAHAM.

INFANTILE SCURVY

Infantile scurvy—known on the Continent as Barlow's disease—is identical in its pathology with the adult form of the disease, its special clinical features being due to the anatomical and physiological peculiarities of early life.

Ætiology.—The disease usually appears between the eighth and twelfth months—both sexes being equally affected. As in adult scurvy, the essential cause is the absence from the dietary of a sufficiency of anti-scorbutic vitamin. Any heating of milk reduces the amount of vitamin C present. Certain commercial processes in condensing or drying milk may completely destroy the vitamin. Pasteurisation is the least harmful process. In any case the addition of vitamin C to the diet is so easy that it is better to make milk a safe food by some heating process rather than to rely on it as a source of anti-scorbutic vitamin. A few cases have been recorded in which the child had been fed on the breast only; it is probable that in these the mother's diet had been deficient in fresh constituents.

Pathology.—The chief changes are in the neighbourhood of the bones. A section made across a limb at the site of a swelling shows that the periosteum is hyper-vascular, thickened and separated from the subjacent bone by a layer of partially organised blood clot. There is no sign of inflammation, and no hard bone is formed in the periosteum, except in very long-standing cases; in which circumstances the muscles surrounding the bone may be infiltrated with blood or serum, and look sodden. The bone exhibits rarefaction, and may be fractured. There may be hæmorrhagic effusions into the joints or serous cavities. The organs exhibit no characteristic change.

Symptoms.—The onset is gradual, the first symptoms noticed being often a refusal of food, along with fretfulness and restlessness. There is a tendency for the child to resent being handled. Meanwhile the general nutrition is usually unimpaired, and the child's colour is often fresh and healthy looking. After a variable period the more prominent symptoms appear. The most striking of these is extreme tenderness of the legs, which causes the child to scream loudly when touched or even when approached. In a well-marked case some swelling will be found, usually of the lower end of the femur or upper end of the tibia. Involvement of the arm bones is much rarer. The skin over the swelling is often tense and glossy, and may be slightly œdematous; but there is no local heat. Soft crepitus may be elicited on handling the limb, indicating a fracture or a separation of the epiphysis. In some cases hæmorrhage takes place into the orbit, giving rise to proptosis and ecchymosis of the eyelid. Rarer sites of hæmorrhage are around the ribs, clavicles or bones of the skull.

Changes in the gums are not nearly so pronounced as in adult scurvy, and are not usually present, unless some teeth have been cut; in that case the gum around them is usually swollen and of a purplish colour. Petechiæ and subcutaneous ecchymoses are very rare in infantile scurvy, and hæmorrhage from mucous membranes is not common. Hæmaturia, however, is not infrequent, and red blood cells, on microscopical examination, are nearly always present. Fever is not a conspicuous feature, but may be present if

extensive hæmorrhages have taken place; it rarely exceeds 102° F. The blood changes are the same as have been described in the adult form of the disease.

Diagnosis.—This is easy in a well-marked case, provided the leading features of the disease are known to the observer. The screaming of the child on examination, the swelling and tenderness of the legs, and the condition of the gums leave no doubt as to the nature of the affection with which one has to deal. All cases, however, are not so pronounced in type. Not infrequently one encounters mild or incipient forms which it is easy to overlook. In these, tenderness when the child is handled, or when it is put in the bath, may be the only symptom. In other cases again, slight sponginess around the incisor teeth may also be present, or one may have to deal with an apparently causeless hæmaturia. In any case in which there is doubt two points will help. One is the nature of the feeding. If this has been of such a kind as is known to favour the development of the disease the diagnosis will be greatly strengthened. The other point is the application of the therapeutic test. If the symptoms present are really due to incipient scurvy then they will certainly disappear rapidly so soon as appropriate treatment is begun; if they fail to do this, then some other condition must be thought of.

Infantile scurvy may be mistaken for rheumatism, although the mistake should not occur if it be remembered that acute rheumatism is hardly ever seen below the age of 2. The distinction between scurvy and suppurative periostitis or epiphysitis is much more difficult, especially if the gum changes are absent. A very high temperature and much constitutional disturbance are against scurvy. The nature of the diet will also be of weight in the diagnosis. A skiagram will be of great assistance in coming to a conclusion. In scurvy the shadow due to subperiosteal hæmorrhage, and a sharp dark epiphyseal line, are characteristic.

The absence of swelling in the affected limb and of the other symptoms of scurvy should distinguish those cases of infantile paralysis in which there is much tenderness of the paralysed leg, and the blood examination should enable one to differentiate a case of acute leukæmia or chloroma.

Prognosis.—This is quite favourable, provided the disease is recognised in time and proper treatment adopted. Nothing in therapeutics is more striking than the rapidity with which such patients improve on a change of diet, although some degree of thickening of the bones may persist for a long time. Death, when it occurs in the more severe cases, is usually the result of intercurrent disease, such as broncho-pneumonia and chronic diarrhœa, although sudden hæmorrhage, cardiac failure or exhaustion may occasionally lead to a fatal issue.

Treatment.—The first step is to bring the disease under control by administering vitamin C in concentrated form as ascorbic acid. This can be given in tablets by mouth, crushed just before use, in a dose of 50 to 100 mg. daily for 2 or 3 days for an infant of 9–10 months. During this period dietetic changes can be made, such as the introduction of orange juice or tomato juice, the institution of mixed feeding (baked potato is particularly valuable), and a change from any over-heated milk or milk product to plain milk just brought to the boil for safety. In very severe cases ascorbic acid can be given intravenously. Iron is useful if there is anæmia present.

Scorbutic infants should be handled carefully, and the clothing so made

that it can be easily taken off and on. If it is necessary to move the child about it should be carried on a pillow. The affected limb should be steadied by light splints or wrapped in wet towels, which, if allowed to dry in position, afford considerable support. In mild cases a covering of cotton-wool secured by a light bandage is sufficient protection.

RICKETS

Definition.—Rickets is a disease of nutrition occurring in early childhood. It mainly affects the growth of the bones, but may be accompanied by tetany in some cases. Associated nutritional disorders produce anæmia and a tendency to catarrh of the mucous membranes in many instances.

Ætiology.—Various theories have been held in the past as to the cause of rickets, but it is now clear that it is essentially due to absence of vitamin D in sufficient amounts to promote adequate calcification of growing bones. The fault is usually dietetic and not only because of deficiency of vitamin D containing foods but also because excess of carbohydrate promotes more rapid growth than calcification can cope with. The ultra-violet rays of sunshine can manufacture vitamin D in the skin. Hence all those conditions which prevent the free access of unfiltered sunshine to the skin of the growing infant may be regarded as predisposing to rickets.

Pathology.—The chief changes are in the bones. Section through the end of a long bone shows that ossification, instead of proceeding in an orderly way, is greatly disorganised. In the zone of proliferation of the cartilage the cells show excessive multiplication, and are arranged irregularly instead of in columns. A broad bluish area results, which is the cause of the thickening of the epiphysis. In addition to this, calcification between the cells is defective, the affected area shows excessive vascularity, and the new bone formed is soft and deficient in lime. The whole process has been summed up in the statement that "there is an excessive preparation for ossification and a defective accomplishment of it." In addition, the vascular layer of the periosteum is thickened and the marrow congested.

Chemical analysis shows that the bones contain only from 30 per cent. to 50 per cent. of calcium, instead of the normal 60 per cent. or more. They may show signs of old or recent fracture. Other organs show no characteristic change.

Symptoms.—The disease can rarely be recognised before the sixth month. Amongst the earliest indications to attract attention are restlessness and irritability, sweating about the head, especially when asleep, and a tendency on the part of the child to kick off the bedclothes at night. There is no wasting, indeed the infant may be abnormally fat, though usually flabby and pale. The appetite is capricious. An early sign, found sometimes as early as three months, is *cranio-tabes*: this is a curious softening of the bones of the occipital region.

As the disease progresses, it will be found that dentition is delayed, and that changes in the bones become manifest. They first show themselves in the epiphyses of the ribs, which enlarge and form a row of knobs down the sides of the chest (the *rickety rosary*). Enlargement of the epiphyses of the

bones of the limbs then takes place, being most conspicuous at the lower end of the radius.

The softening of the bones leads to various deformities. The chest sinks in at the line of junction of the ribs and cartilages, so that a broad groove forms, running downwards and outwards towards the axilla (Harrison's sulcus). The bones of the limbs bend, the femur curving forwards and outwards, and the tibia bending sharply forwards and often also outwards at its lower third; there may also be a curving of the upper part, leading to "bow-leg." The humerus and bones of the forearm may become bent in an outward direction, as the child sits supporting itself on the hands, and the clavicle may show a sharp kink at the junction of the inner and middle third. The pelvis becomes flattened. Greenstick fractures of the limb bones are not uncommon.

The skull shows striking changes. It is usually somewhat enlarged, elongated and flattened on the vertex (box head), the anterior fontanelle remaining widely open long after the normal period of closure at the eighteenth month. There may be pronounced thickening of the frontal and parietal eminences, leading to the so-called "hot-cross bun" or bossed head, especially in cases complicated by anæmia with enlarged spleen.

The muscles are often so weak and flabby that paralysis is simulated, and the ligaments may be so lax that the limbs can be bent into almost any position ("acrobatic rickets"). In consequence also of the laxity of ligaments, kyphosis often develops in the lower lumbar region (rickety spine).

The blood usually shows a varying degree of anæmia of the hypochromic type, and in a few cases the changes are so profound as to resemble those met with in chlorosis. Biochemical studies show a raised blood phosphatase, a lowered blood phosphorus and in severe cases a lowered blood calcium.

The digestive system is usually deranged. Chronic diarrhœa with pale, offensive stools is not uncommon. The abdomen is distended so that the child has a pot-bellied appearance. In the production of the distension, muscular weakness, intestinal fermentation, and the pushing down of the diaphragm by the sinking in of the chest all play a part. The edge of the liver can often be felt at a lower level than normal, partly from displacement and in part from enlargement through fatty change. The spleen is also palpable in a considerable number of cases, although this is due more to its being pushed down than to actual enlargement.

In the respiratory system bronchial catarrh is very often present, and not uncommonly results in broncho-pneumonai. In the nervous system the disease shows itself by general nervousness and irritability, and in some cases by the development of laryngismus stridulus, tetany, or even convulsions, of all of which rickets is a strong predisposing cause.

The clinical picture here outlined refers to fully developed rickets, which is becoming a rare disease in Britain, save for certain areas. X-ray examination confirms the clinical findings in the established case, but also it reveals changes in the growing ends of the long bones at a stage when clinical examination is essentially negative. This mild type of rickets is relatively common, and indeed some observers regard it as almost "physiological" in the sense that for calcification to be optimum in the rapidly growing bones of the small child a high degree of "saturation" with vitamin D and calcium seems to be necessary. X-ray studies have also drawn attention to the fact

that the clinical diagnosis of rickets based upon enlarged epiphyses and bow-legs, for example, is often unreliable.

Diagnosis.—In a fully developed case the diagnosis is easy. Early cases, and those in which the rickety element is overshadowed by some complication, such as broncho-pneumonia or diarrhoea, are more apt to be overlooked. The suggestive points will be delayed dentition, an open fontanelle, and the presence of the rickety rosary. A skiagram will show some cupping of the diaphysis; the epiphyseal line will be irregular and ill-defined, and the epiphysis itself poorly ossified. There will also be a tendency to osteoporosis throughout the whole bone. The appearance of the epiphyses of the carpus and tarsus may be retarded.

The rickety head is apt to simulate hydrocephalus, but in the latter condition the skull is more globular, and bulges above the ears, the fontanelle is tense, and the eyeballs, in marked cases at least, pushed downwards. The kyphosis of rickets may be mistaken for spinal caries; but in the former the bend straightens out as a rule when the child is held up by the armpits. In severe cases this may not happen, and a radiograph may be required to settle the diagnosis. Bowing of the legs in the toddler is often more due to muscular development than to bent bones. If the muscular weakness is pronounced infantile paralysis may be imitated; but the history, the retention of the reflexes, and the presence of other signs of rickets should prevent mistakes.

Prognosis.—Rickets is not fatal *per se*, and usually passes off spontaneously after the second year, although the deformities of the bone may persist for a long time. Even these, however, have a wonderful way of righting themselves without any special treatment. On the other hand, rickets is a very serious complication of other diseases, especially of broncho-pneumonia and diarrhoea, and adds greatly to their fatality if present, so that the dictum of Sir William Jenner that "in its indirect results rickets is one of the most fatal diseases that peculiarly affect childhood" is still perhaps true.

Treatment.—Rickets can be prevented if the child is properly fed and cared for. Breast-feeding for the first 9 months is the best safeguard, provided that the mother's diet is satisfactory; but it must always be remembered that the disease is apt to develop in children who are kept *too long* on the breast. After weaning, the premature and excessive use of starchy foods must be avoided. Care should be taken that the diet contains an adequate amount of animal fat. Plenty of fresh air, sunlight and exercise are also important factors in prophylaxis. It is probable that all infants in temperate and cold climates require a daily supplement of cod-liver oil to give 800 international units of vitamin D daily for the first two years of life. The same dose should be used throughout to give a relatively larger amount to the small infant.

If the disease has already developed, the diet should be altered in accordance with the requirements indicated above, the most important point usually being to increase the allowance of cow's milk, which should not fall below $1\frac{1}{2}$ pints per diem during the second year of life. Yolk of egg is also a valuable food. Cod-liver oil and halibut-oil (or one of the artificial substitutes containing vitamin D) are most useful, having a specific influence on the disease; but iron may also be given with advantage if there is anæmia. It is wise to start with a pure vitamin D concentrate in adequate dosage for about a

month to bring the disease under control. Sun-baths or exposure to the rays of the mercury-vapour lamp have a definitely curative effect.

To prevent bending of the legs, long splints may be applied, projecting beyond the feet, so as to make standing impossible. Orthopædic treatment may be required for the more permanent deformities. Alimentary and respiratory complications should be treated by the measures appropriate to them.

LATE OR ADOLESCENT RICKETS

This term is applied to a disease apparently identical with ordinary rickets in its bony changes, but which sets in much later, usually between the ninth and fourteenth years. The patient may have been the subject of ordinary rickets in earlier childhood—hence the use of the term “recrudescent rickets”—or the disease may have appeared at the later age for the first time. Nothing is known of its causation, but in some cases it is associated with fibrosis of the kidneys (renal rickets) or with coeliac disease.

The manifestations of the disease are practically confined to the skeleton, the long bones being particularly affected. The epiphyses become much enlarged, and pronounced deformities ensue as the result of bending. The skull escapes almost entirely, and there is no tendency to any disease of the internal organs, except in the renal cases, or to complications.

The disease is not dangerous to life; but the deformities may be lasting. The general treatment is the same as that of ordinary rickets; but most cases will require the help of the orthopædic surgeon.

“Fœtal” and “congenital” rickets are ambiguous terms which have been loosely used to cover several distinct pathological conditions, amongst which are achondroplasia, mollities ossium, and osteogenesis imperfecta. They are best avoided. So-called “scurvy-rickets” and “acute rickets” are identical with infantile scurvy, although rickets often coexists with the latter, seeing that both are due to faulty feeding.

ALAN MONCRIEFF.

BERIBERI

Synonyms.—Polyneuritis Endemica; Hydrops Asthmaticus; Kake ; Barbers.

Definition.—A nutritional disease related to deficiency in vitamin B₁, and occurring most frequently in tropical regions where polished rice constitutes the main article of dietary. It is characterised typically by neurological lesions involving especially the peripheral nerves of the limbs, or by acute congestive heart failure.

Ætiology.—The rice-eating populations of India, Japan, Malaya, the Dutch East Indies and Philippine Islands are mainly affected, but the disease is also endemic in Newfoundland and Labrador, where the population eat chiefly white wheaten flour. Though the disease is specially rife amongst people eating polished rice, rice *per se* is not essential, any dietary deficient in the antineuritic vitamin B₁ being a potential source of danger. Parboiled and undermilled or husked rice are not deficient in vitamin B₁. During

milling the husk, pericarp and germ, which are rich in protein, fat, phosphorus and vitamin B₁ (see p. 475) are removed, leaving the white polished rice poor in these constituents. Milled rice, white flour, breakfast cereals, macaroni, spaghetti and cane sugar contain practically no vitamin B₁. This vitamin, known also as "aneurine" or "thiamine," was synthesised in 1937 in crystalline form (1 mg. = 300 international units), and is now available for therapeutical purposes. It is mainly found in yeast, marmite, whole seeds, the germ of cereals, pulses and nuts. Aneurine is a precursor of co-carboxylase, which removes, by oxidation, an important intermediary product of carbohydrate metabolism—pyruvic acid—from the tissues and blood. The chemical tests for the estimation of pyruvic acid and aneurine are dealt with on p. 476. Excess of pyruvate can be demonstrated in the blood in beriberi, the value rising from a normal of 0.4–0.6 mg. to 1–7 mg. per 100 c.c. The quantity normally present in the cerebrospinal fluid is also increased. When no complicating factor is present, 5 mg. of vitamin B₁ will restore the blood to a normal value in 10 to 15 hours. B₁ is readily absorbed and is stored in the liver, kidneys and heart, but the storage capacity is limited and clinical experience indicates that symptoms may appear in man in a few weeks with a B₁ deficient diet.

Pathology.—Cases of so-called "dry beriberi" rarely come to autopsy. In "wet beriberi" there is an acute congestion of the mucosa of the duodenum and lower end of the stomach, sometimes associated with pin-point hæmorrhages. The peripheral nerves show a Wallerian degeneration, with possibly an axonal degeneration of the neuron involved. The sheath of Schwann may exhibit multiplication of its nuclei and invasion by leucocytes. The vagus, phrenic and sympathetic system may present stigmata of degeneration, and sometimes the anterior-horn cells of the spinal cord and the nuclear connections of the vagus in the floor of the fourth ventricle are said to be implicated. The cardiac muscle may show degenerative changes, while the naked eye appearances are those of fatty degeneration associated with dilatation and hypertrophy, especially involving the right side. Nutmeg-liver œdema of the soft tissues and effusions into the serous cavities are common. Wenckebach regarded œdema of the heart muscle with resulting loss of contractility, and not involvement of the vagi, as responsible for the cardiac condition. Weiss and Wilkins point out that the myocardium shows an unaltered water content, with "hydropic" degeneration of the muscle and conductive fibres, and increase in intercellular substances. Adrenal hypertrophy, similar to that described by McCarrison in avian polyneuritis, has been recorded in man. In experimental animals the process underlying the nervous manifestations is a dysfunction and non-inflammatory; it has in consequence been suggested that the term "neuropathy" is more accurate than "polyneuritis." In long-term deficiency, however, damage to tissues may ensue which cannot be repaired merely by correcting the vitamin deficiency.

Symptoms.—There is generally a latent period of some two to three months before deficiency symptoms become manifest. Typically the onset is gradual, being characterised in the initial stages by epigastric discomfort, nausea and perhaps vomiting and diarrhoea. Later, polyneuritis, with palpitation, shortness of breath and weakness develop, the subsequent clinical picture varying according to involvement of the peripheral nerves, the vagus, or the sympathetics. The disease runs an afebrile course, except

possibly in its early stages. Recurrences are common. Several different types are described :

(1) **LARVAL OR AMBULATORY CASES.**—There is numbness of the legs with patchy anæsthesia and diminution of knee-jerks, all of which quickly disappear if the condition is recognised and a more varied diet containing vitamin B₁ be given.

(2) **ORDINARY BERIBERI.**—(a) *Wet form.*—Prodromata include paræsthesias and heaviness of the limbs. The knee-jerks are at first exaggerated and then lost. Tenderness of the calf muscles, blunting of sensation, and patches of hyperæsthesia and anæsthesia appear. The patient becomes weak, and cannot rise from the squatting position. Varying grades of œdema, at first involving the subcutaneous tissues over the tibiæ, appear and, later, effusions into the serous cavities with water-logging may develop. Shortness of breath, dyspnœa and tachycardia indicate involvement of the eardiac nerves. There are manifestations of dilatation of the heart, especially the right side (see pp. 889, 989, 990). Several factors may contribute to the œdema : (1) intracellular œdema associated with failure of cell nutrition ; (2) cardiac failure or an increased tension of the capillaries ; (3) decreased plasma proteins ; and (4) secondary renal insufficiency. When the nervous manifestations are slight and the patient can still do muscular work, œdema is more likely to develop. Sudden death may occur without clinical evidence of cardiac involvement. (b) *Dry form.*—This is similar to the above except that œdema is absent and the disease runs a more chronic course. The onset is insidious, gastro-intestinal disturbances may be absent, the dominant features being wasting and weakness of the muscles, associated perhaps with cardiac irritability. Wrist drop and the high-steppage gait may be present, but though the patient walks unsteadily there is no true ataxia or Rombergism. Clinically, the disease closely resembles alcoholic neuritis and that encountered in pellagra, both of which are now regarded as being due to a deficiency in B₁. Wet beriberi may develop at any time, but this is less likely if the neuropathy is sufficiently severe to keep the patient resting. Lesions of the cranial nerves other than the vagi and phrenics are very rare.

(3) **ACUTE FULMINATING BERIBERI.**—Cardiac symptoms may predominate from the onset, or suddenly supervene in either the wet or dry forms. Cardiac decompensation of the congestive variety (see p. 889) rapidly ensues. Alteration of the voice or aphonia resulting from pressure of the dilated right auricle on the recurrent laryngeal nerve has been reported. The diaphragm also may be paralysed. Owing to renal insufficiency there may be a scanty urine containing albumin and casts, and a high blood urea which falls as the output of urine increases with treatment. Death may supervene in a few hours to a few days.

(4) **INFANTILE BERIBERI.**—This disease occurs especially in the Philippine Islands and Japan, where it is responsible for many deaths in breast-fed infants whose mothers are affected with latent or clinical beriberi. More than 50 per cent. of cases show symptoms between the third and fourth weeks of life. The disease occurs in both acute and chronic forms. In the latter gastro-intestinal features like anorexia, vomiting, diarrhœa or constipation occur, associated with wasting, pallor, œdema, mainly involving the face and extremities, dyspnœa, and other evidences of cardiac insufficiency.

Aphonia or an altered cry is often striking, and loss of knee jerks is present in 75 per cent. of cases. In the acute form death may occur with great rapidity, the infant developing convulsive attacks, suffering severe colicky pain and presenting cyanosis, dyspnoea and muscular rigidity.

(5) OTHER CLINICAL TYPES.—These include *ship's beriberi*, which may be associated with scurvy (vitamin C deficiency) and is now rare amongst sailors, and *pellagroid beriberi*, in which there is a mixed deficiency, the skin and mucosa membrane lesions being cured with nicotinic acid and the neuritic manifestations with vitamin B₁. *Secondary beriberi* may be associated with (1) gastro-intestinal diseases leading to defective absorption of vitamin B₁, (2) chronic alcoholism, or (3) pregnancy, diabetes, febrile states, or diseases increasing metabolism which lead to a relative deficiency by increasing the demand for B₁.

Epidemic Dropsy, which is met with in India and other parts of the tropics, occurs in epidemics amongst rice eaters and is often classified as a type of beriberi. Gastro-intestinal features, especially diarrhoea, are common. Some degree of fever is, however, generally present, progressive anaemia is frequent, a vascular mottling of the skin over the tibia and inner side of the thigh is not uncommon, as well as a tendency to hæmorrhages involving the mucous membranes. Clinical evidence of neuritis is not obvious; the knee jerks are generally normal, and cutaneous anaesthesia and deep hyperaesthesia of the muscles absent. Some hold it is due to toxic substances developed in degenerating or diseased rice; others that it is caused by poisons in mustard oil. Its relationship to nutritional oedema in which there is a lowering of serum albumin and decreased colloidal osmotic pressure of the blood, does not appear to have been adequately investigated. Though simulating wet beriberi in some respects, there are obvious clinical differences, and the disease is probably not a pure B₁ deficiency.

Diagnosis.—Wet beriberi has to be diagnosed from cardiac failure, nephritis and severe ancylostomiasis, while the dry form has to be differentiated from alcoholic and arsenical neuritis, tabes dorsalis and progressive muscular atrophy. The dietetic history is important, and multiple cases of neuritis, especially if associated with oedema, should always suggest beriberi. Vitamin B₁ is greatly decreased or practically absent from the urine in cases of beriberi, and this test (p. 476) may determine the diagnosis in doubtful cases. Volhard's diuresis test may also be helpful, since there is water retention in beriberi.

Prognosis.—This depends on the institution of appropriate treatment at a reasonably early stage of the disease. Aneurine cures the early neurological manifestations of "dry" beriberi, and relieves many of the advanced cases, but progress is often very slow and permanent disability may result if treatment be too long delayed. It improves the cardio-vascular disturbances in "wet" beriberi, and is often a life-saving measure in acute fulminating beriberi with cardiac failure, provided it be given intravenously in adequate dosage. If the patient survives the first two weeks and an adequate maintenance dosage of B₁ be continued, recovery ensues. In infants the disease tends to run a rapid course and shows a high mortality unless promptly treated. Tachycardia, oedema and congestive heart failure not infrequently precede death. Cases which return to their polished rice diet are liable to relapses and sooner or later die of the disease.

Treatment.—**PROPHYLACTIC.**—Prophylactic measures consist in providing a balanced dietary adequate in B_1 , i.e. 1–2 mg. daily. An allowance of 10–15 I.U. (international units) or 3.3–5.0 micrograms per 100 calories of food intake suffices for most purposes. Any condition which increases the metabolic rate requires an increase in vitamin B_1 . These include (1) a diet high in starch, sugar or alcohol, (2) fever, and (3) hyperthyroidism. In institutions where polished rice or white bread is the main article of dietary, under-milled or parboiled rice and whole-wheat flour should be substituted. The addition of cooking soda to vegetables should be avoided, since boiling in the presence of alkali destroys B_1 , though heat alone does not. The water in which vegetables have been cooked contains vitamin B_1 and can with benefit be added to soup.

CURATIVE.—Dietary is an all-important factor in recovery, and the introduction of crystalline vitamin B hydrochloride (aneurine hydrochloride : thiamine hydrochloride) has revolutionised treatment.

Crystalline vitamin B_1 .—In ordinary cases this drug is administered orally, but the intravenous route is indicated (1) in severe and fulminating cardiac cases, (2) when there is reason to believe absorption is defective, and (3) in liver disease. The optimum oral dosage remains to be determined, but 5–10 mg. daily for mild cases and 20 mg. daily for moderately severe cases should prove adequate. In severe cases, especially those with cardiac features, 20–50 mg. should be given each day by the intravenous route for the first two weeks, followed by a similar dosage daily taken by the mouth. In fulminating cardiac cases, 100 mg. may be immediately injected and this should be repeated until relief is obtained, after which the dose may be reduced. Hawes has used much larger doses in moribund patients with dramatic effects.

Careful nursing and absolute rest in bed are essential, and when there is right-sided cardiac failure venesection is of definite value. Small feeds containing marmite should be given two-hourly. Subsequently a low carbohydrate diet rich in B complex and adequate in other vitamins is advisable. Yeast, marmite, wheat germ, rice polishings, wholemeal flour, barley, oatmeal, liver, kidneys and other glandular organs serve as a satisfactory source of B_1 . Orange and tomato juice and milk, butter, eggs and cream should also be included in the dietary of such cases.

In infantile beriberi the mother should receive vitamin B_1 treatment, and artificial feeding instituted for natural feeding or a healthy wet-nurse employed. Vitamin B_1 should be administered in adequate dosage, and the two-hourly feeds reinforced with marmite.

When there is polyneuritis involving the lower limbs a cradle should be put over the feet, while splinting may be necessary to prevent muscular contractures. After the acute symptoms have subsided, massage and electrical treatment may help to restore the circulation and muscle tonus.

PELLAGRA

Synonyms.—Mal de la Rosa ; Mal del Sole ; Maidismus ; Psilosis pigmentosa ; Malattia della Miseria ; Asturian Leprosy ; Alpine Scurvy.

Definition.—Pellagra is a chronic relapsing disease occurring especially

in maize eaters, due to a deficiency in certain factors contained in the vitamin B₂ complex, *i.e.* B₂ (riboflavin), B₆ (adermin), and B₇ (nicotinic acid). Clinically, it is characterised by buccal and gastro-intestinal disturbances, psychical and nervous features, and a symmetrical eruption especially affecting areas of skin exposed to the sun's rays or to friction.

Ætiology.—Pellagra (*pelle*, the skin; *agra*, rough) prevails endemically in the Southern States of the U.S.A., lower Egypt, Turkey, Roumania, the Balkans, Spain and Italy, and has been reported from India, China, Japan, parts of Africa, Mexico, West Indian Islands, etc. People of any race, age or sex are susceptible, and the malady is more common amongst the poorer classes. The incidence of the disease is greater in the spring. It occurs particularly amongst maize eaters, and in poorer communities living on cereals containing a low protein content or protein of low biological value. Following the work of Elvehjem on canine black tongue, nicotinic acid (B₇) and its amide have been found to clear up the early dermal changes and mucous membrane lesions in pellagra and to relieve many symptoms referable to the central nervous system. Certain coenzymes contain nicotinic acid amide (Warburg and von Euler), and severely ill pellagrins usually have a low coenzyme content in the blood (Vilter and Spies). It has been suggested that an interference with general cellular metabolism may result from a deficiency of available respiratory enzymes. When infection or hyperthyroidism increase the oxidative activity of the body and when the enzymes which facilitate such activity are wanting owing to a deficiency of their precursors, a deficiency syndrome follows. Other factors in the B₂ complex, *i.e.* riboflavin (B₂) and adermin (B₆), as well as proteins, are also essential in preventing pellagra and probably have a closely inter-related function (see pp. 477, 478). Sporadic cases of true pellagra occur in alcoholics or are secondary to disease of the alimentary tract. They arise from mal-absorption of pellagra-preventing factors or from deficiencies in the dietary prescribed. Irrespective of whether the development of pellagra follows poverty, erroneous dietary habits, dietary idiosyncrasies, organic disease, chronic alcoholic addiction, or some combination of these factors, the lesions, symptoms and methods of treatment are essentially the same (Spies).

Pathology.—Emaciation is marked and the internal organs, including the heart and spleen, are small and atrophic. Skin lesions consist of an initial erythema involving the superficial layers, terminating later in a true exfoliative or exudative dermatitis, associated with pigmentation. Stomatitis and glossitis with ulceration of the tongue, denudation of its epithelium and ultimate atrophy may ensue. The jejunum is congested and atrophic, and small superficial ulcers involving the jejuno-ileum, colon and rectum are described. The mesenteric glands may be enlarged. Demonstrable pathological changes in the nervous system are generally slight, but there may be a subacute combined degeneration of the cord involving the posterior and lateral tracts, and especially Clarke's column (Wilson). Degeneration of the anterior-horn cells in the lumbar region, and subacute inflammation of the ganglion cells in the posterior roots are described, while Briauchi recorded meningeal thickening and adhesions, atrophy of the cerebrum, and hydrops of the ventricles and subarachnoid space. More than 50 per cent. of pellagrins show achlorhydria which is histamine-fast, but Castle's intrinsic factor appears to be secreted normally by the pyloric glands and

megalocytic anæmia is rare. The total white count is generally normal in uncomplicated cases, there is often a lymphocytosis, and some degree of secondary anæmia is common. The cerebro-spinal fluid exhibits no abnormality.

Symptoms.—The exact incubation period is unknown, and it should be realised that prodromal symptoms may recur over long periods before the classical oral or dermal features develop. In this stage a definite history is most important in making a correct diagnosis. Generally there is a history of having lived for a long period on (1) maize or other cereals poor in protein of high biological value, or (2) a diet high in fat and carbohydrate, and poor in proteins and vitamins, such articles as red meat, eggs, milk, fish, fresh vegetables and fruit being lacking.

Prodromal Symptoms.—These include anorexia, loss of weight and strength, dyspepsia, flatulence, vomiting, sensations of burning or discomfort in the epigastrium, constipation or diarrhoea, insomnia, headache, palpitation, vertigo, numbness, forgetfulness, nervousness, mental irritability and mental confusion. Later, characteristic involvement of skin, alimentary tract and nervous system may supervene, but all three systems are not necessarily affected in any one pellagrin, while the sequence and the severity of the symptoms show considerable variation in individual cases.

Alimentary features.—The glossitis and stomatitis which usually appear early in the disease are diagnostic. In the early stages the tip and sides of the tongue are red and swollen; later the whole organ becomes fiery red (beet tongue) and inflamed, with lateral indentations from the teeth. Deep ulcers may develop on the sides and tip, while the dorsum becomes covered with a thick grey membrane, perhaps containing Vincent's organisms. A similar condition may involve the buccal mucous membrane, palate, gums and the muco-cutaneous surface of the lips. Hot, spiced and acid foods increase the ptyalism and the burning sensations felt in the tongue, pharynx, oesophagus and stomach. Other symptoms include nausea, vomiting and abdominal discomfort, flatulence and distension, especially after food. The bowels may act normally or be even constipated in the early stages, persistent diarrhoea being characteristic only of the advanced cases. In the latter the stools are non-fatty in type, diarrhoea occurs at all hours, and is often associated with colicky pain and tenderness. Sigmoidoscopy may reveal a proctitis. Associated vaginitis and urethritis are not uncommon.

Skin lesions.—Their distribution is on the back of the hands, wrists and forearms, the dorsum of the feet, the face, neck, upper part of the chest, under the breasts and in the perineal regions—in short, over those areas directly exposed to the sun's rays or friction. Commencing as an erythema resembling a severe sunburn, there is redness, swelling and tension of the skin, followed by itching, burning and possibly bleb formation, while later, a deeper dermatitis develops with desquamation and exfoliation. Pigmentation and thickening of the dermis result, but finally atrophy supervenes, the skin becoming wrinkled, inelastic and thinned. Pathognomonic features of pellagrous eruptions are their absolute symmetry and their sharply demarcated pigmented borders—the hyperkeratotic border of Merk.

Nervous system.—The early mental symptoms, which are often regarded as functional, include depression, apprehension, irritability, headache, insomnia, and bilateral burning sensations involving the extremities or

other parts of the body. Later these mental symptoms are accompanied by rigidity, tremor of the tongue, coarse tremors of the limbs and head, athetoid movements and cramp; while numbness and paralysis of the extremities are common. The reflexes which at first are generally increased, later become decreased, and finally are often entirely absent. The gait may be spastic or ataxic, and cord involvement or peripheral neuritis due to associated B₁ deficiency may be factors in the production of the neurological picture. If improperly treated, insanity often results. Retardation of growth occurs in children, but fortunately neurological complications are not common in them.

The course of the disease is generally afebrile and characterised by definite attacks alternating with remissions extending over many years unless a proper diet be maintained.

Diagnosis.—In classical pellagra the glossitis, stomatitis and the characteristic skin lesions make the diagnosis easy, but these features occur only in the well-established disease and it is the subclinical cases or those presenting vague prodromal manifestations which are so important to recognise early. A reliable history of dietary deficiency is important, and the rapid amelioration of gastro-intestinal and mental symptoms following nicotinic acid therapy will confirm the diagnosis. The urinary test for nicotinic acid excretion devised by Harris and Raymond (p. 478) may clinch the diagnosis in doubtful cases. Pellagra sine pellagra may be confused with sprue or ergotism, while erythema multiforme and dermatitis venenata may cause difficulty.

Prognosis.—In endemic pellagra if patients receive modern treatment and a maintenance diet adequate in vitamin B₂ complex and good biological protein, the mortality should be low. In the past, about 40 per cent. have been estimated to develop mental trouble, and many of these died in asylums. Fever is an unfavourable sign, and in the absence of intercurrent disease occurs either as a terminal event or in the fulminating form known as typhoid pellagra, which is characterised by intense prostration, tremor, muscular rigidity, convulsions and death. In secondary pellagra, the prognosis depends on rectification of a faulty diet and treatment of the underlying alimentary trouble.

Treatment.—**PROPHYLACTIC.**—The addition to a pellagrin's diet of red meat, milk, eggs and substances rich in vitamin B₂ complex, e.g. brewer's yeast and marmite, will prevent the disease.

CURATIVE.—Rest in bed, a high caloric, nutritious diet low in carbohydrate but rich in protein, and foodstuffs containing vitamin B₂ complex are desirable. The diet should include fresh milk, lean scraped red meat, liver, canned salmon, tomato juice, fresh fruit and vegetables. Articles which have been found to possess curative value when given in large dosage include Brewer's yeast (75–100 g. daily), marmite (30–60 g. daily), wheat germ (250–300 g. daily), ventriculin (200 g. daily) and liver extract (75–100 g. daily). The discovery of the curative effects of adequate doses of nicotinic acid on many of the manifestations of pellagra has revolutionised the treatment of the disease. The drug is administered by the mouth, in tablet form and in divided doses, the daily dosage ranging from 200–1000 mg., 500 mg. being generally effective. After ten days the dosage may be decreased. Flushing, burning and itching, nausea, vomiting and colic may follow,

especially if the drug is given in large dosage on an empty stomach. Nicotinic acid also stimulates gastric activity and acid secretion, and is liable to elicit a mild histamine-like type of reaction. The mucous membrane lesions, including pellagrous glossitis, stomatitis, vaginitis, urethritis and proctitis, are healed and bowel function restored to normal, the early erythematous lesions are blanched, while the early and late mental relapse symptoms are greatly benefited. The chronic skin lesions, however, are not cured by nicotinic acid therapy. Associated symptoms of peripheral neuritis are not relieved by nicotinic acid, but both pain and numbness disappear after daily injections of 50–100 mg. of crystalline vitamin B₁ (Spies).

Riboflavin is indicated if there is angular stomatitis or cheilosis; the oral dosage is 5–15 mg. daily. No toxic effects have been described following oral administration.

TROPICAL MACROCYTIC ANÆMIA

Synonyms.—Nutritional Macrocytic Anæmia; Tropical Megalocytic Anæmia.

Definition.—A severe nutritional anæmia, megalocytic in type, especially affecting pregnant women in the tropics and subtropics, and responding specifically to marmite or liver extract therapy. Non-hæmolytic and hæmolytic types are encountered.

Ætiology.—The disease affects both sexes but is especially common in women during the child-bearing period owing to the superadded nutritional demands of pregnancy and lactation; it develops during the latter half of pregnancy. It has been reported from India, China, Africa and Macedonia. The malady is found in rice-eaters in the southern half of India, where it affects all communities and grades of society (Wills). In Macedonia, it is prevalent in the refugee population, whose diet is poor in animal proteins, which suggests that an amino-acid deficiency may be the basis of the syndrome. Castle holds that lack of extrinsic factor in the diet is responsible, but Wills and Evans believe it is due to deficiency in a new hæmopoietic factor contained in crude liver and autolysed yeast. The factor concerned has not been identified with any constituent of the vitamin B₂ complex. Frequently the condition is associated with chronic malarial splenomegaly, which introduces a superadded hæmolytic factor through excessive phagocytosis of abnormal red cells by a hypertrophied and pathological reticulo-endothelial system resulting from repeated malarial infections over many years (Fairley).

Pathology.—In uncomplicated non-hæmolytic cases the organs are pale and may show fatty infiltration secondary to the anæmia. In fatal cases, there may be cardiac dilatation associated with fatty changes in the myocardium, a congested enlarged liver, œdema and other evidence of cardiac decompensation. Megaloblastic hyperplasia of the red marrow is found, and Ehrlich polychromatic megaloblasts are demonstrable in smears or sections. In cases of hæmolytic type associated with splenomegaly, there is, in addition, a generalised hypertrophy and hyperactivity of the reticulo-endothelial cells, which may contain malaria pigment and phagocytosed red cells, fine hæmosiderin deposits in the parenchyma cells of the liver and spleen, and a decrease of lymphoid tissue in the latter organ in which the

Malpighian bodies may have disappeared. Hæmorrhages may be found in the skin and scrous or mucous membranes. The bone marrow shows general hyperplasia of the myeloid cells, with increase in the activity and numbers of hæmocyto blasts and erythroblasts. Basophilic and polychromatic megaloblasts are common, but ripening sufficient to produce a really pink cytoplasm in a cell with a finely stippled primitive nucleus is a rarity. Pathological changes in the precursors of the white cell series are common, and megakaryocytes are liable to be atypical or scanty.

The condition is one of panmyelopathy in which some more primitive cell type than the megaloblast must be implicated. The reticulo-endothelium lining the marrow sinusoids is the ultimate source of erythrocytes, leucocytes and platelets, and it appears not improbable that the deficiency factor no less than malaria itself is exerting its deleterious influences on primitive reticulo-endothelium.

Symptoms.—In the uncomplicated *non-hæmolytic type* the symptoms are essentially those associated with a grave anæmia. The patient often first seeks advice for cardiac palpitations, giddiness, shortness of breath, weakness on walking and physical fatigue. Sore tongue, anorexia, vomiting, flatulence, abdominal distension and diarrhœa may be complained of, and fever or cough may or may not be present. Physical examination generally reveals a well-nourished patient with pale mucous membranes, a low blood pressure and rapid pulse, and often hæmic cardiac murmurs. Later frank congestive cardiac decompensation (see p. 889) may ensue. The blood picture resembles that of pernicious anæmia with megalocytes and often nucleated red cells present in the blood smears. Red cell counts of between 500,000–1,000,000 erythrocytes per c.mm. are not uncommon. The colour index generally exceeds unity. The mean corpuscular volume is increased, and the Price-Jones curve shows a shift to the right, and an increased variability and mean corpuscular diameter. Leucopenia is common, the reticulocytes are not increased, the serum bilirubin values are normal and the fractional test meals show that, unlike pernicious anæmia, the oxyntic cells retain their power of secreting HCl after the administration of histamine.

In the *hæmolytic type* of tropical macrocytic anæmia, certain features are superadded. The spleen is invariably enlarged and hard but not tender. Petechial eruptions involving the skin, epistaxis and bleeding gums or bleeding from other mucous membranes occur in about 25 per cent. of cases, and are invariably associated with thrombocytopenia. An icteroid tinting of the skin or conjunctivæ is not uncommon, while hyperbilirubinæmia and dark brown stools are characteristic findings. The blood picture resembles in many respects the megalocytic anæmia already described, but reticulocytosis is the rule, and megalospherocytosis may be found which is not the case in the non-hæmolytic type. Leucopenia and thrombocytopenia are frequent findings. Apart from cardiac decompensation, the more common complications include uterine sepsis in the puerperium, *B. coli* infections of the genito-urinary tract, and respiratory infections; the last is predisposed to by the increased pressure on the diaphragm exerted from below by the pregnant uterus and greatly enlarged spleen, which so many of these patients present. Typical paroxysms of malarial fever at this late stage are rare, and parasites are not demonstrable between attacks.

Diagnosis.—An adequate hæmatological investigation is essential in

diagnosis. The non-hæmolytic type has to be distinguished from other megalocytic anæmias. It differs from pernicious anæmia in that HCl is secreted in response to histamine injections, and nervous manifestations are absent, while the atrophic, distended abdominal parietes, marked loss of weight and the bulky pale fatty stools so characteristic of tropical sprue are not observed in tropical macrocytic anæmia. The hæmolytic type clinically resembles acholuric family jaundice, but there is no family history, the corpuscular fragility is not increased to hypotonic saline solutions, and the anæmia is of an entirely different type in the two diseases.

Prognosis.—Balfour estimated the death-rate as 40 per cent. before the introduction of liver therapy. With modern treatment and in the absence of complications patients whose condition is diagnosed at a reasonably early stage should recover completely. The non-hæmolytic type responds more readily than the hæmolytic type, in which very large doses of liver parenterally may be necessary.

Treatment.—**PROPHYLACTIC.**—Prevention depends on the adoption of a well-balanced diet containing adequate amounts of protein of good biological value and vitamin B₂ complex.

CURATIVE.—Uncomplicated cases of non-hæmolytic type generally respond to marmite (Wills) in a dosage of 30 grammes daily, to liver extract by the mouth equivalent to 1 lb. of fresh liver daily, or to daily injections of 2 c.c. of injection of liver (campolon type). Maximal reticulocytosis develops about the seventh to ninth day, and provided treatment is maintained satisfactory blood regeneration follows.

In the hæmolytic variety, or where complications exist, much larger daily doses of marmite (60 grammes) or preferably of parenteral liver extract (6–8 c.c.) are necessary, and in severely ill patients, it is often advisable in addition to parenteral liver therapy to give blood transfusions in order to tide the patient over the critical few days before specific therapy initiates the hæmopoietic response. Successful termination of labour and the cessation of lactation decrease the nutritional demands on the body and may result in spontaneous cure, but it is important to remember that skilled medical and nursing attention during the puerperium, and the daily examination of the patient for the onset of complications such as cardiac failure and pulmonary infections may result in saving the patient. Throughout treatment a nutritious diet containing meat, eggs, milk, and foods rich in vitamin B₂ complex is desirable.

N. HAMILTON FAIRLEY.

SECTION VII

DISEASES OF THE ENDOCRINE GLANDS

DISEASES OF THE PITUITARY GLAND

APART from its own special functions, the pituitary gland has a stimulating effect on most of the other ductless glands, which latter tend to atrophy after removal of the pituitary gland (hypophysectomy). The influence, however, is reciprocal and hyper- or hyposecretion of the other endocrine glands influences the activity of the pituitary. The hypothalamus, on either side of the third ventricle, contains many nerve nuclei which are connected with the pituitary gland. They provide the mechanism for an intimate relationship between hypothalamic stimuli and pituitary function.

The posterior lobe secretes two hormones, pitressin and oxytocin. The former has a vaso-pressor action, is anti-diuretic, and produces an increased urinary excretion of chloride. The latter, oxytocin, produces contraction of the pregnant uterus. Recently, it has been shown that pitressin causes contraction of the non-pregnant uterus. The pars intermedia secretes a specific katabolic factor (Collip), and the melanophore expanding hormone.

The anterior pituitary gland appears to secrete 10 or more hormones, but it is uncertain whether they are all distinct chemical substances. It has been postulated that one hormone may have different actions under varying physiological circumstances. Description is facilitated by assuming the existence of separate hormones :

1. Growth-producing hormone.
2. Lactogenic hormone. This initiates and maintains mammary secretion.
3. Thyrotrophic hormone (thyrotrophin). This produces (a) hyperplasia of the thyroid gland and hypersecretion of thyroxine; and (b) exophthalmos, even after thyroidectomy.
4. Gonadotrophic hormone (gonadotrophin). This factor has been chemically separated into two components, Prolan A and Prolan B, which under certain conditions produce different gonadotrophic reactions. Thus, Prolan A stimulates development of the Graafian follicles and of the spermatic tubules; whereas Prolan B produces luteinisation of mature follicles, or of the theca of immature follicles, and hyperplasia of the interstitial cells of the testis or ovary.
5. Diabetogenic hormone. This hormone produces hyperglycæmia, glycosuria and ketonuria. The effect appears after 2 or 3 daily injections, and owing to the appearance of anti-bodies cannot be sustained ordinarily for more than a few weeks. If, however, the daily dose of hormone is progressively increased, permanent diabetes results even when injections cease, and the islets of the pancreas are then seen to have undergone degeneration. The diabetogenic hormone can act in the absence of the adrenal glands;

but their presence augments the diabetogenic effect, since they undergo cortical hyperplasia (associated adrenotrophic hormone) and this itself tends to produce hyperglycemia. A diabetogenic effect is best seen on the hypophysectomised depancreatized dog (Houssay dog). Secretion of the diabetogenic hormone may be produced by electrical stimulation of the ventro-medial nuclei of the hypothalamus.

6. Glycotrophic hormone (Young). This hormone can prevent the hypoglycemic action of insulin, without, however, having the power to produce hyperglycemia. It appears to act by directly antagonising the action of insulin, that is, by preventing the oxidation of glucose in the peripheral tissues, by inhibiting glycogen formation in the muscles, and by facilitating glucose formation from hepatic glycogen (glycotrophic or, better, glucotrophic).
7. Ketogenic hormone. This produces ketonemia, ketonuria and an increase of liver fat. It can be separated from diabetogenic anterior lobe extracts.
8. Pancreatotrophic hormone. This produces hyperplasia of the islets of Langerhans, and increased secretion of insulin. Its separate entity is not certain, and the initial action of the diabetogenic hormone in certain species appears to be pancreatotrophic.
9. Adrenotrophic (corticotrophic) hormone. This produces hyperplasia of the adrenal cortex. As with other trophic hormones, the effect is best demonstrated after the hypoplasia, or atrophy, of the adrenal cortex that follows hypophysectomy. It is associated with, but can be separated from, the thyrotrophic and growth hormones.
10. Parathyrotrophic hormone (parathyrotrophin). This has been described but its existence is not firmly established.

ACROMEGALY

Definition.—Acromegaly is a condition due to a hypersecretion of the growth hormone of the anterior pituitary gland. It is characterised by enlargement of the hands and feet, and of the bones and cutaneous tissues of the face, and by splanchnomegaly. It is frequently superimposed on gigantism.

Ætiology.—The disease occurs at any age but usually before 40, and in both sexes. There is a mild familial type. The immediate cause is an excessive secretion of the growth hormone.

Pathology.—The primary lesion is an adenoma, or hyperplasia, of the chromophil cells. Secondary enlargement of the adrenal cortex, the thyroid and the parathyroids may be present. The testes and ovaries are usually atrophic. The islets of the pancreas may be hyperplastic in the initial phases, and later undergo atrophy. Diffuse lymphoid hyperplasia is frequent. All the viscera are enlarged.

Symptoms.—The patient may first seek advice because of increasing size of the hands and feet, or of a blunting and distortion of facial features, or of visual disturbance due to a pituitary tumour. The latter is associated with optic atrophy, bitemporal hemianopia, progressive loss of vision and severe headaches. Ocular palsies may result from pressure on the third, fourth or sixth nerve.

The enlargement of the extremities is partly due to bony enlargement and thickening, but there is also overgrowth of the soft tissue. The vault of the skull may be somewhat thickened, but considerable bony overgrowth is more common in the base of the skull and in the facial bones. The overgrowth of the lower jaw leads to prognathism and spreading of the teeth. The vertebræ undergo changes, and kyphosis and scoliosis are common. The soft tissues of the face, nose, and lips undergo hypertrophy, which together with the bony changes, may transform the facial appearance. The skin and subcutaneous tissue are thickened, and the sebaceous and sudoriferous glands hypertrophied, producing a greasy perspiring skin. The hair too is thick and greasy, and may be abundant over the trunk. Enlargement of the tongue leads to difficulty in articulation, and enlargement of the larynx produces a deep voice. Speech is also sluggish and memory poor. The general behaviour may be characterised by apathy and lack of initiative. Generalised muscular hypertrophy may initially be associated with great strength, but later weakness and atony result. The heart is enlarged, but hypertension or hypotension may occur.

Complications and Sequelæ.—(1) Sex Function. Impotence in the male, and amenorrhœa in the female, are common complications, caused by destructive encroachment of the eosinophil cells on the gonadotrophic basophil cells. (2) Thyroid. Although exophthalmic goitre is a rare complication, a raised basal metabolism is not infrequent, and an excess of endogenous pituitary thyrotrophic hormone produces enlargement of the thyroid in some 50 per cent. of patients. In the later phases, myxedema may supervene. (3) Adrenals. The development of hair on the face and body in females (hirsuties) suggests a pituitary corticotrophic stimulus. It is only rarely present in a severe degree, and may not develop until some years after the onset of the acromegaly. (4) Diabetes Mellitus. This disorder is present in a small proportion of patients; but some degree of intermittent or chronic hyperglycæmia with glycosuria, in the absence of diabetic symptoms, may be detected in some 50 per cent. The pituitary diabetogenic hormone is probably responsible. (5) Diabetes Insipidus or Diabetes Tenuifluis. There may be in different patients, or in one patient in different phases of the disorder, evidence of deficiency or excess of the anti-diuretic hormone. (6) Mental Changes. Depression, irritability, negativism, melancholia, mania and delusional insanity are possible complications.

Diagnosis.—The increase in size of hands and feet, and thickening and blurring of the facial features, with prognathism, makes diagnosis easy, especially if gigantism is already present. Osteitis deformans is a bony disorder which distorts the vault of the skull and does not affect the facial bones. In acromegaly, radiographic examination may reveal an enlargement of the sella turcica, which if associated with optic atrophy or bitemporal hemianopia, indicates a pituitary eosinophil tumour.

Prognosis.—The course is gradually progressive, with intermittent phases of apparent arrest of the pituitary hyperfunction. These phases may be prolonged over many years. As myxedema may follow exophthalmic goitre, so hyperactivity of the pituitary may be succeeded by hypoactivity, with secondary hypofunction of the thyroid and adrenal glands.

Treatment.—If there is progressive involvement of the optic nerves, with danger of complete blindness, the treatment is surgical removal of the

pituitary tumour. Otherwise deep radiation of the pituitary region should be tried first, and relief results in some 50 per cent. If sight is not threatened, and there appears to be an arrest of pituitary hyperfunction, treatment is symptomatic, including hormone substitution where indicated, *e.g.* thyroid for myxœdema, testosterone for impotence, and œstradiol for amenorrhœa. Exophthalmic goitre may be treated by radiation of the thyroid, or thyroidectomy. True diabetes mellitus will need dietetic regulation and insulin, but symptomless glycosuria can be ignored.

GIGANTISM

This is a condition of rapid and excessive growth of bone resulting, among other manifestations, in a height above normal. Like acromegaly, it is due to excessive secretion of the growth hormone by the eosinophil cells of the anterior pituitary (hyperplasia or tumour), but this hypersecretion operates in childhood, or adolescence, before the epiphyses of the long bones have united. If the hypersecretion persists, acromegaly will be superimposed on the gigantism. In uncomplicated gigantism, there is no sharp dividing line between normal tall people and pathological giants, and the characteristic of tallness is probably a familial and racial feature dependent upon constitutional hyperactivity of the anterior pituitary. Eunuchoid individuals, as well as pre-pubertal castrates, are often excessively tall. This may be due to two factors: (1) growth hormone acting over a longer period, since the union of the epiphyses is delayed; and (2) hyperactivity of the anterior pituitary secondary to failure of gonadal function, assuming the latter to be primary.

The treatment of pathological gigantism is the same as for acromegaly, namely, radiation of the pituitary gland, or surgical removal of a pituitary neoplasm. Inhibition of pituitary activity by large doses of testosterone, or œstradiol, may be of some benefit.

CUSHING'S SYNDROME

Definition.—A condition of virilism in females (or of feminisation in males) associated with adiposity, hypertension, diabetes mellitus, plethora, and softening of the bones.

Ætiology.—The disease is commonest in the second and third decades but may occur at any age. It is much more common in females than males. The immediate cause is hyperfunction (or dysfunction) of the pituitary basophil cells and of the adrenal cortex.

Pathology.—Cushing postulated that the primary lesion was an adenoma of the basophil cells of the anterior pituitary gland. While it is true that an adenoma, or even a carcinoma, of these cells is found in some cases, in others the primary lesion appears to be adenoma or carcinoma of the adrenal cortex, carcinoma of the thymus gland, or an ovarian arrhenoblastoma. In nearly all cases, whatever the apparent primary lesion may be, there is also found hyperplasia of the adrenal cortex and hyalinisation of the pituitary basophil cells. The latter change is considered to be a fundamental one by Crooke, who discovered it. It can, however, be secondary and reversible, since removal of an adrenal tumour produces a return to clinical normality.

Symptoms.—Virilism is shown by cessation of menstruation, loss of hair of the head, and growth of hair on the face and body, as in the male; feminisation is indicated by testicular atrophy and impotence, and by mammary development. For a fuller description the reader is referred to the sub-section on Diseases of the Suprarenal Glands. In all cases the adiposity is diffuse, but it is especially noticeable on the face, trunk, and upper arms and thighs. It is occasionally a painful adiposity. Where the skin has been stretched by fatty deposits, *e.g.* in lower abdomen, thighs, breasts, and axillæ, there are *linea distensæ*, which are not white but of a deep red colour. The face is plethoric and of a dusky tinge, suggesting a polycythæmia basis, which is not necessarily substantiated by a red cell count. The anterior aspects of the legs show bluish mottling with contrasting patches resulting in a marble appearance, from which is derived the dermatological name, *cutis marmorata*.

The bones are rarefied (seen in X-ray photographs) and softened, so that the vertebrae are compressed, and the patient develops kyphosis and round shoulders, with a diminution in height. Lordosis helps to accentuate an adipose pendulous abdomen, and may give rise to troublesome backache. The blood pressure is raised, and there may be a secondary ischæmic nephritis. In a few patients, fatal malignant nephrosclerosis has been recorded. Diabetes mellitus may be present in varying degrees of severity, and those patients who manifest no diabetic symptoms invariably show a delayed fall in blood sugar in the carbohydrate tolerance test. Pigmentation of the orbits and nipples may be present. Migrainous headaches are not infrequent, but changes in the optic nerves or visual fields are rare, since basophil adenomas are usually microscopic in size. The thyroid gland may be enlarged, but there is rarely evidence of hyperthyroidism.

Complications.—The patients are liable to intercurrent infections, especially staphylococcic.

Diagnosis.—Adipose corpulent women with plethoric faces, rounded shoulders, and hirsutism, suggest the diagnosis. Radiograms may show osteoporosis, but the sella turcica is usually not enlarged. Glycosuria and hypertension are additional features. Hirsutism is of male distribution, but quite frequently not excessive. The possibility of an adrenal tumour is suggested by considerable hairiness, gross enlargement of the clitoris, and a gross excess of androgenic hormone in the urine (*e.g.* more than 20 mg. of 17-ketosteroids per 24 hours). In doubtful cases, iodoxyl (pyelectan, uropac, uroselectan) radiographic examination, or perirenal insufflation, or even laparotomy is called for (see adrenal section). Thymus tumours may be excluded by radiographic examination of the chest, and ovarian tumours (a rare cause) by bi-manual examination. The urinary calcium excretion may be increased, but the serum calcium is not raised, as in the case of hyperparathyroidism.

Prognosis.—Incomplete forms of Cushing's syndrome are not at all unphases of appearance. They do not necessarily call for any special be prolonged or questionable whether they are more correctly regarded as goitre, so hyper-ality than as pathological.

Treatment.—In the absence of treatment, the course is usually downhill, but only gradually so. As with acromegaly, there may be with danger arrest of the process for many years. If an adrenal tumour is

removed surgically, in the absence of malignant recurrence the patient may return to complete normality. In the case of basophil adenoma, deep radiation applied to the pituitary gland may be followed by remarkably good results, with disappearance or considerable amelioration of most symptoms, including the diabetes mellitus.

Treatment.—An adrenal tumour should be removed surgically. A thymus neoplasm is malignant and deep radiation of the thymus area is unlikely to prove of more than temporary benefit in such cases. In the absence of proof of any primary lesion outside the pituitary gland, a basophil adenoma is assumed, and deep radiation applied to the pituitary gland. Unilateral adrenalectomy for a supposed bilateral hyperplasia of the adrenal cortex is illogical, and cannot produce appreciable amelioration.

INFANTILISM

Synonym.—Levi-Loraine Syndrome.

Definition.—Infantilism is a condition of deficient somatic growth and sexual development that might, however, be regarded as normal for a much younger individual. The term also implies the persistence of infantile characteristics in the adult and the failure of proper development of primary and secondary sexual characteristics. The term was first used by Loraine in 1871 in connection with a case of infantilism associated with tuberculosis. It was later applied by Levi (1908) to hypopituitarism beginning in childhood. Brissaud extended the term to include infantilism associated with hypothyroidism (Brissaud's syndrome), but this is a more complicated and less well-defined disorder.

Ætiology and Pathology.—Usually in life there is no gross lesion and autopsies are rare, since the uncomplicated condition is not incompatible with good health. Experimental and biological evidence indicates a deficiency of pituitary eosinophil cells (growth hormone), and less certainly a deficiency of basophil cells (gonadotrophic). Occasionally a third ventricle tumour, or pituitary craniopharyngioma, or chromophobe adenoma may be the cause.

Symptoms.—In childhood, the patient is perfectly formed but somatic growth is much below the usual rate. Development of the primary and secondary sexual characteristics at puberty does not occur, and the genital organs remain infantile throughout adult life. The condition, however, is not absolute, and varying degrees of sexual development are met with. Although the epiphyses tend to remain open long after the normal time of closure, the ultimate height is well below normal, as the secretion of growth hormone is deficient. Intellectual development is usually normal and sometimes above normal standards, but emotional development and behaviour pattern tend to retain immature characteristics. The patients are usually slender and have graceful limbs, ankles and wrists. The skin and hair are of smooth silky texture, and the general appearance is becoming.

Diagnosis.—The condition should be differentiated from other forms of dwarfism (which see).

Prognosis.—This depends upon the time at which treatment is commenced, but in general hormone therapy can only produce a trend towards normality. Health and normal function, other than sexual, is maintained even in the absence of any treatment.

Treatment.—Growth hormone, 2 c.cm. (20 rat units) intramuscularly, three times a week, should precede gonadotrophic therapy, although the danger of the latter producing premature union of the epiphyses appears to be largely theoretical. The therapy should be continued for months or years, with intervals to permit antibodies that appear in the blood after several weeks' injections, to disappear. Gonadotrophins, 500 units intramuscularly, twice weekly, are given for six weeks, and repeated after an interval of two months. In the absence of adequate response, testosterone in males, and hexoestrol in females, will prove a potent form of substitution therapy as far as secondary sexual characteristics are concerned.

DWARFISM

Definition.—A condition of sub-normal height well below the normal range. It is the opposite of gigantism. Although no other abnormality may be present, the use of the term is also extended to include a variety of conditions, of which deficient height is only one feature.

Ætiology and Pathology.—The essential feature is a deficiency of pituitary eosinophil cells and of their growth-promoting hormone. The condition is quite comparable to that found in a strain of congenital dwarfed mice, in which the dwarfism and deficiency of eosinophil cells follows a Mendelian recessive genetic distribution in successive families. Occasionally in man a pituitary or other intracranial destructive neoplasm may be the cause.

Symptoms.—In uncomplicated cases there are no features other than retardation of growth. In some patients, especially girls, this may be finalised by the premature union of epiphyses at puberty, *e.g.* 12 years of age. If, on the other hand, sexual development is infantile, the condition is that of infantilism (see above). In Fröhlich's syndrome, adiposity is an essential feature. Dwarfism may also be a feature of Simmond's cachexia, if the condition is due to a pituitary craniopharyngioma commencing in childhood. Progeria (meaning prematurely old), is a name given by Hastings Gilford, in 1904, to a rare condition comparable to Simmonds's cachexia in childhood, and associated with an old, wizened countenance, infantile sex organs, dwarfism, alopecia, absence of breasts, and a parchment-like skin. The condition is probably of pituitary origin, but its exact pathology is uncertain. Pathological sexual precocity is associated with premature union of epiphyses and ultimate dwarfism, although initial growth rate may be rapid.

Diagnosis.—With simple failure of growth, or in infantilism, the relative proportion of arms, legs, and trunk may be normal. In achondroplasia, a familial condition of defective endochondrial ossification, the arms and legs are short compared with the body (human dachshund), and the nose is broad and flat. Non-endocrine causes of dwarfism are rickets, renal rickets, fragilitas ossium, coeliac disease, pancreatic disease, von Gierke's glycogen disorder, vitamin deficiency, and achondroplasia.

Prognosis.—Where the epiphyses are ununited, and treatment is started early with a potent growth hormone preparation, the prognosis is fair, but apparent unresponsiveness is met with.

Treatment.—The essential treatment is growth hormone, which, however, is quite useless if radiograms show the epiphyses of the long bones to have

united. 2 c.cm., or 20 rats units, may be given intramuscularly three times a week for six weeks, and repeated after an interval of some weeks. Thyroid by mouth is also helpful, even when there is no obvious hypothyroidism. When hypogonadism is also present in boys, gonadotrophic hormone and/or testosterone, contrary to general belief, tends to accelerate growth and somatic development, and does not appear to produce epiphyseal union in ordinary therapeutic doses.

SIMMONDS'S DISEASE

Synonyms.—Pituitary Cachexia ; Hypopituitarism.

Definition.—A disorder due to destruction or atrophy of the anterior pituitary gland, and manifested by cachexia, anorexia, subnormal metabolism, and hypogonadism.

Ætiology.—The disease is more common in women since the commonest cause is atrophy of the anterior pituitary resulting from a local vascular lesion during the puerperium. Multiparæ are especially prone. It may, however, occur at any age and in either sex associated with a pituitary or parapituitary tumour.

Pathology.—Simmonds's original case showed atrophy and fibrosis of the anterior pituitary gland as a result of an embolus in the main artery in a fatal case of puerperal fever. The vascular lesion is, however, more commonly thrombosis of the pituitary veins, following severe uterine hæmorrhage at parturition. Suprasellar cystic tumours and chromophobe adenoma are other important causes, and rarely malignant metastases, tuberculosis, syphilis, and exanthemas. An unusual but important ætiological occurrence is simply diminution in the relative number of eosinophil cells. As in the case of hypophysectomy, the gonads, thyroid and adrenal cortex are hypoplastic or atrophic. The viscera are diminished in size in contrast to the splanchnomegaly of acromegaly.

Symptoms.—Weakness, wasting, and anorexia are cardinal features, but of equal importance is the invariable failure of sex function. Thus, in the female, amenorrhœa is associated with a hypoplastic or infantile uterus, and, in the male, the gonads and penis fail to develop or, if already adult in size, they undergo atrophy. In both sexes the secondary sexual characteristics, *e.g.* pubic, facial and axillary hair, are lost, and the eyebrows and hair of the scalp also become thin and lustreless, or disappear. The skin is pale and dry, and may become wrinkled, giving a senile facies, known as progeria. The lower jaw may become atrophic (opposite of prognathism), and the teeth decay and fall out. The low metabolism, *e.g.* —40 per cent., is manifested by a subnormal temperature and hypersensitivity to cold. Bradycardia and hypotension are usual features. The blood sugar is also subnormal and the carbohydrate tolerance usually increased. Spontaneous hypoglycæmic attacks occur, and may be fatal. Anæmia and a relative lymphocytosis, with perhaps some degree of eosinophilia, are not uncommon.

If the disorder commences in childhood, the lack of growth hormone results in failure to grow, although the epiphyses remain ununited in adult life, and there is failure of sexual development.

Complications.—Pulmonary tuberculosis may follow prolonged inanition.

Apathy, inertia, and somnolence are characteristic but may progress to melancholia, with disorientation of time and place. Optic atrophy results from tumours.

Diagnosis.—The well-developed syndrome cannot escape recognition if the disorder is kept in mind. Cachexia is not always a feature. Minor and incomplete manifestations are more easily missed, but not if the possibility of the disorder following a puerperium in which there is severe hæmorrhage and (or) infection is remembered. Migrainous headaches can occur even in the absence of a pituitary or parapituitary tumour, but radiographic examination of the sella turcica and examination of the fundi for optic atrophy should not be omitted. The condition is often mistaken for myxœdema (which see), but without justification, and the response to thyroid alone is never adequate, as it is in myxœdema.

There are many features in common with Addison's disease, but pigmentation in Simmonds's cachexia is either absent, or very slight, and is never present in the mucous membranes. Anorexia nervosa in the late stages may show all the features of Simmonds's cachexia, and it is probable that there is an inhibition of pituitary activity via the hypothalamus. A similar mechanism may explain examples of incomplete Simmonds's disease following shock or psychic trauma. Anorexia nervosa may therefore be considered as one of the psychological causes of an organic endocrine disease, Simmonds's cachexia. Nevertheless, the initial and fundamental cause of anorexia nervosa is psychogenic, and there are essential differences in the clinical history and manifestation of the two disorders. Thus anorexia nervosa usually occurs in young adults, more often in females, and it is possible to elicit a history of psychic trauma, shock, disappointment, or emotional upset. In contrast to the apathy of Simmonds's cachexia, these patients are restless and perform feats of activity far beyond their apparent strength; the loss of sexual hair is rarely extreme and may not occur; in contrast, the trunk and perhaps the face is covered by diffuse downy hair. The twenty-four hourly output of 17-ketosteroids is low in Simmonds's cachexia, *e.g.* 2 mg. (normal 5 to 12 mg.); and the insulin sensitivity test (intravenous injection of 2 units of insulin) shows a rapid fall of blood sugar to low levels, *e.g.* 30 mg. per 100 c.cm., and a delayed recovery curve. Similar results of both tests may be found in the late stages of anorexia nervosa, but initially the results are normal in this condition. In myxœdema, the output of ketosteroids is low, but the fall in blood sugar after intravenous insulin is somewhat retarded. The Kepler test for adrenal function (see also Addison's disease) often shows as low an index in Simmonds's disease as in Addison's disease.

Prognosis.—There is usually progressive deterioration, but patients with minor manifestations following pregnancy may recover spontaneously. Treatment is beneficial, but it is not easy to provide complete substitution therapy, and the cessation of therapy is often followed by relapse. Patients are usually sterile, but should pregnancy supervene and parturition be normal, clinical recovery may result.

Treatment.—Complete substitution therapy should consist of testosterone in the male, œstradiol and progesterone in the female, desoxycorticosterone and cortical extract to replace deficient adrenal function, thyroid, and the anterior pituitary anti-insulin or glycotrophic factor (not yet available). Gonadotrophins may be effective in the male, but are rarely so in

the female. In practice, I have found testosterone very effective in both males and females, producing increased strength, and well-being, and a positive nitrogen balance; and in some patients desoxycortone, with or without testosterone, produces good results. The injection of corticotrophic hormone is theoretically indicated but my experience is disappointing. Thyroid should only be given in moderate doses and may prove harmful.

FRÖHLICH'S SYNDROME

Synonym.—Dystrophia Adiposo-Genitalis.

Definition.—A combination of adiposity and hypogonadism, usually occurring at or before puberty, and resulting from pituitary hypofunction, or dysfunction. Dwarfism constituted a third feature in Fröhllich's original description, but it is generally agreed that the diagnosis can also be made with justification in its absence.

Ætiology.—The condition occurs in both sexes, and may be familial. Fröhllich's original case was a boy of 14 with a craniopharyngioma.

Pathology.—A small proportion of cases are due to a parapituitary tumour (cranio-pharyngioma), or more rarely to a chromophobe adenoma of the anterior pituitary. The majority, however, are not associated with a gross pathological lesion, and autopsies are rare. The lesion is sometimes in the hypothalamus rather than in the pituitary, *e.g.* encephalitis, meningitis, syphilis, and hydrocephalus. The syndrome was produced by Cushing in dogs by partial hypophysectomy, combined with trauma to the hypothalamus.

Symptoms.—Adiposity and hypogonadism are the two essential features, but to these may be added in some cases a deficiency of growth hormone and dwarfism. The fat is deposited in girdle and symmetrical fashion, on the abdomen, shoulders, thighs, upper arms, mammary region, mons veneris, face and neck. The adiposity may be present from early childhood, although the syndrome is at its maximum at puberty. The legs and forearms may be thin and graceful, and the fingers are usually narrow, delicate and tapering, but occasionally short. The deposition of fat is of feminine type, so that the bodily configuration of the affected male resembles that of the female. There is often a pad of fat over the lower cervical vertebræ. The skin over the outer aspect of the upper arms, thighs and buttocks shows a blueish-red mottling. Abdominal lineæ distensæ are usually white and not red as in Cushing's syndrome.

Hypogonadism in the male is shown by minute testicles, one or both of which may be undescended, and by a subnormal penis. There is little or no hair over the axillæ and pubis; and, if present in the latter site, it is of feminine distribution, being limited horizontally and not extending upwards to the umbilicus. The skin of the face is smooth, delicate and hair-free, and the complexion good. The voice is high-pitched and may not "break." The walk is feminine, and the buttocks tend to sway from side to side as in the female. The feminine habit of resting the hand on the waist or knee is not uncommon. In the female the uterus is infantile, and amenorrhœa, or scanty menstruation at long intervals, is usual. The breasts are large, but this is caused by fat, and not by glandular tissue. A tendency to sleepiness, like the fat boy in *The Pickwick Papers*, and a craving for sweet things are other

features. The basal metabolic rate is normal. The mental and emotional colouring of the personality is characteristic. Periods of depression and introspection alternate with joyousness, high spirits, and euphoria. The patients are excellent company, and very popular with their school friends. They are usually musical and imaginative, with intellectual ability often above normal.

Complications.—Rarely the syndrome is complicated by the additional features of retinitis pigmentosa, mental deficiency, polydactylism and familial incidence. It is then called the Laurence-Moon-Biedl syndrome, and the patient is usually of the Hebrew race.

Diagnosis.—Unless definite hypogonadism is present, the diagnosis of Fröhlich's syndrome is not justified, but is nevertheless frequently made. This is because of lack of supplementary nomenclature. Puberty adiposity may occur with normal genital development, or even with some degree of sexual precocity, or with some features of Cushing's syndrome. In all cases it is probably endocrinological. A parapituitary tumour is indicated by optic atrophy and enlargement or distortion of the sella turcica, as seen in radiograms.

Prognosis.—The disease may be transitory, the adiposity decreasing with belated sexual development. More often it is chronic, with phases of accentuation and amelioration.

Treatment.—Gonadotrophic hormone, 500 units twice weekly for 6 weeks or more, will tend to produce sexual maturation but rarely influences the adiposity. The latter may be modified by restricted diet and thyroid. It is irrational to employ the latter in doses greater than 1 gr. of the dried gland daily, since the basal metabolism is not subnormal. The adiposity is unlikely to be fundamentally altered by any hormone therapy at present employed. Parapituitary tumours may call for surgical removal if sight is threatened. Deep radiation of the pituitary region may be of benefit, but should not be lightly undertaken.

DIABETES INSIPIDUS

Definition.—Diabetes insipidus is a disturbance of water balance, characterised by polyuria and polydipsia, but due to a destructive lesion of the posterior lobe of the pituitary gland, or of the adjacent part of the hypothalamus.

Ætiology.—The condition is sometimes familial. It is due to a deficient secretion of the anti-diuretic hormone by the posterior lobe of the pituitary. This results from destruction of the lobe, or any interruption of its normal connection with the supra-optic nucleus of the hypothalamus. Such a lesion is followed by degeneration of the pars nervosa, but not of the pars intermedia. The anterior pituitary lobe must be present for diabetes insipidus to result, and it probably has a diuretic action by an indirect effect on metabolism. It is doubtful if the anti-diuretic hormone of the pars nervosa has been separated from the vasopressor hormone. In addition to decreasing the amount of urine excreted, this hormone also increases the amount of chloride excreted in the urine.

Pathology.—The lesion in the hypothalamic-pituitary mechanism may be traumatic, vascular, syphilitic or tuberculous meningitis, primary or metastatic brain tumour, acromegaly, or Hand-Schüller-Christian's disease. The condition may also follow shock, via the hypothalamic mechanism. In the majority of cases, there is no obvious cause (idiopathic).

Symptoms.—The symptoms are polyuria and polydipsia, with the passage of large quantities of urine, *e.g.* 12 litres in 24 hours, of pale colour, and low specific gravity, *e.g.* 1002. The polyuria leads to disturbed sleep and anxiety. The patient loses weight and strength, and may become very emaciated and even bedridden if untreated.

Diagnosis.—Hysterical polyuria may be difficult to differentiate apart from the hysterical background. There is a tendency in this condition, however, for the polyuria to be more marked during the daytime and the patient may sleep throughout the whole night, whereas the polyuria of diabetes insipidus is most troublesome at night. The hysterical patient remains in reasonably good health in spite of the polydipsia and polyuria. Some individuals have a familial hypersensitivity to caffeine diuretics and, if much tea or coffee is drunk, they have polyuria and frequency. Diabetes mellitus is easily distinguished by hyperglycaemia and glycosuria. In chronic nephritis the urine may be voluminous and of constantly low specific gravity, but it contains some albumin and renal casts. A Wassermann reaction to exclude tertiary syphilis is always advisable. A radiogram of the skull, and examination of the optic disks and visual fields should exclude pituitary and parapituitary tumours. The Hand-Schüller-Christian disease is congenital and familial and characterised by exophthalmos, large liver and spleen, yellow-tinted skin, and irregular patches of xanthomatous infiltration of the skull (radiogram).

Prognosis.—The disease is protracted, and if treatment is inadequate the patient becomes emaciated and dies from intercurrent infection.

Treatment.—It is illogical to attempt to restrict the intake of fluid severely, for experimental evidence shows that the primary disorder is the polyuria, and the polydipsia is a secondary attempt to compensate for the loss of fluid. Pitressin should be injected, 10 to 20 units subcutaneously three or more times in 24 hours. Some patients react allergically at the site of injection. Other commercial brands may then be tried, but if local reactions persist, the treatment will not be effective even if continued, as the hormone tends to be destroyed at the site of injection. A more prolonged effect may be obtained by the intramuscular injection of 1 c.cm. (5 units) of pitressin tannate in oil, a single injection being effective for 24 hours or longer; and this method is preferred by many patients. Nasal insufflation of the dried powder is effective, and is carried out from a curved glass tube with two open ends or with a rubber pressure bulb attached. The patient learns to know the optimum amount of powder and frequency of application. Nasal jelly and application of the fluid on cotton wool in the nostrils are other methods. As with insulin, the dose of pitressin must be increased during periods of infection, *e.g.* influenza.

DIABETES TENUIFLUUS

Definition.—A condition of supernormal secretion of the posterior pituitary antidiuretic hormone, manifested by diminution in the volume of urine excreted and an absence of thirst. *Tenuifluus* means "flowing slenderly," and the condition is the opposite of diabetes insipidus (tasteless urine). The latter condition might be better termed diabetes multifulus (copious urine—flowing greatly).

Ætiology and Clinical Features.—The malady is due to excessive secretion of the anti-diuretic hormone of the pars nervosa of the pituitary. It is probable that the condition occurs rarely as an uncomplicated entity, as does diabetes insipidus, although in the comparatively few occasions that it has been observed, it has appeared to be part of a pituitary syndrome. It may be found with pituitary or parapituitary tumours, with Fröhlich's syndrome, and with other varieties of pituitary adiposity. Aeromegaly may be associated either with diabetes insipidus, or with diabetes tenuifluus, and one may give place to the other according to the phase of the disease. In one such case of the latter, Ellinger, Hare and Simpson observed, for the first time, that there was an excess of anti-diuretic hormone in the cerebrospinal fluid. The daily intake of fluid was small, and the output of urine even smaller, the difference apparently being explained by an obviously excessive perspiration, in contrast with the dry skin of diabetes insipidus. It is interesting to note that radiation of the pituitary gland resulted in a normal and balanced fluid intake and output, and a disappearance of excessive perspiration and of the excess of antidiuretic hormone from the cerebrospinal fluid.

The mechanism of perspiration may not always compensate for a discrepancy between intake and output of fluid, and fluid may be retained, with a resulting increase in weight, at any rate for a time. This may explain the premenstrual gain of weight, which may occur with normal women, but which is much greater in women with pituitary obesity. The subsequent post-menstrual loss of weight is associated with a diuresis. A disorder of water balance is also one factor in certain types of pituitary obesity, as is suggested by the response to mercurial diuretics, or sometimes to the mere adoption of the prone position.

Complications.—E. I. Jones recently described a syndrome, in a man of 26, which he attributes to hyperactivity of the posterior lobe of the pituitary gland. The main features were hypertension, hyperchromic anæmic, achlorhydria, and impaired carbohydrate tolerance. Melanophore-expanding vasopressor, and antidiuretic substances were present in the urine (Noble and others).

Diagnosis.—An abnormally small daily excretion of urine in the absence of cardiac or renal disease suggests diabetes tenuifluus, especially if accompanied by excessive perspiration for which no ordinary cause is obvious.

Treatment.—Radiation of the pituitary gland appears beneficial.

S. L. SIMPSON.

DISEASES OF THE THYROID GLAND

In the absence of convincing evidence as to the existence of dysthyroidism, a division of thyroid disorders into hypersecretion and hyposecretion is at present acceptable. In the case of both, the age incidence may influence the clinical features. The essential hormone of the thyroid gland is usually considered to be thyroxine, the p-hydroxyphenyl ether of tyrosine. The colloid of the gland is thyroglobulin, a protein to which iodine is attached. On hydrolysis this yields the α -amino acids thyroxine and diiodotyrosine. Harington believes that the true active secretion contains thyroxine and diiodotyrosine linked to form a peptide. The activity of thyroglobulin is proportional to its total iodine content and not to the thyroxine contained therein. Further, the iodine content of thyroxine is essential to its physiological action.

Unfortunately a clinical classification of thyroid diseases has not a clearly defined morbid anatomical basis. This is not unrelated to the fact that hyperplasia of the gland, in the absence of sufficient iodine, may be present with the clinical manifestations of hyposecretion rather than hypersecretion. According to Marine, the thyroid gland is a very labile tissue, with a single definite morphological cycle influenced by the balance between the need for iodine and its availability. An absolute or relative deficiency of iodine leads to hypertrophy and hyperplasia of the thyroid epithelium and loss of colloid. A subsequent adequate supply of iodine produces involution to a resting epithelium and much colloid. This cycle can repeat itself, but a prolonged iodine deficiency may lead to irreversible atrophy of the gland. Experimental evidence indicates that iodine can prevent most thyrotrophic or goitrogenic agents from being effective.

Clinically there are two main types of hyperthyroidism, exophthalmic goitre, and toxic adenoma. Hypothyroidism may result in cretinism, or myxœdema, according to whether the deficiency is present at birth or develops after a period of normal thyroid function.

EXOPHTHALMIC GOITRE

Synonyms.—Graves's Disease; Parry's Disease; Basedow's Disease; Primary Thyrotoxicosis.

Definition.—Hyperactivity and hypersecretion of the thyroid gland, usually manifested by tachycardia, tremor, loss of weight, nervousness, sweating, exophthalmos, enlargement of the thyroid, and raised basal metabolic rate.

Ætiology.—The disease is more common in females than males, in the ratio of 6 to 1. This is probably associated with the greater lability of the endocrine system in the former, as indicated by the not infrequent physiological transient enlargement of the thyroid at puberty, at menstruation, and the menopause. The malady is commonest in the second and third decades, but it may occur in childhood or old age. Puberty or the menopause may be periods of initiation.

Mental stress, anxiety, shock and sexual neurosis are often precursors of the disease, but a constitutional vulnerability of the thyroid to such stimuli is probable. The latter is also indicated by a familial predisposition. Infection aggravates pre-existing hyperthyroidism, and sometimes appears to initiate the disease.

Pathology.—The cuboidal epithelial cells undergo hypertrophy and become columnar. They also divide and multiply (hyperplasia), and may project in folds into the follicles, giving a lace-like pattern. The follicles are almost emptied of colloid unless iodine has been given. Adenomas may be present. There is a generalised lymphatic hyperplasia and lymphoid infiltration of the thyroid itself. The thymus is usually enlarged. The liver may show areas of necrosis or atrophy, and is often depleted of glycogen. Experimentally, pituitary thyrotrophin will produce similar pathological changes and a raised basal metabolic rate in guinea-pigs and man. Nevertheless, it has not been possible to demonstrate such a hormone in the blood of patients with hyperthyroidism.

Symptoms.—The excessive secretion of thyroxine has wide systemic effects, and also disturbs the nervous stability of the patient. Many of the symptoms appear to result from overactivity of the sympathetic nervous system.

Cardio-vascular system.—Tachycardia in some degree is invariable, and is usually associated with palpitation. Extra-systoles may be present, and if the disease is of long standing or in people over 40, auricular fibrillation is not infrequent. Capillary pulsation may be seen, and vasomotor instability is evidenced by a tendency to blush or the appearance of a characteristic patch of redness over the neck and upper sternum. The carotid and brachial vessels pulsate visibly and forcibly. The systolic pressure is usually raised and the diastolic is normal or diminished, resulting in an increased pulse pressure.

Nervous system.—There is a characteristic tremor of the hands, noticeable on being asked to hold out the hands, or in writing, or in lifting a cup. An anxiety neurosis is a frequent and almost invariable accompaniment of exophthalmic goitre. The patient is also restless and unstable, and finds it difficult to remain in one position for any length of time. Conversation too is desultory and, although there is often a hyperacuity of perception and conception, this is offset by an inability for sustained effort or concentration. Increased sensitivity and sensibility trouble the patient and her associates or family, and emotional distress is common. Occasionally psychotic manifestations develop, especially paranoia and acute mania, with suicidal tendencies, but rarely does this happen in the absence of a constitutional predisposition. Sweating is often excessive, manifested by the hot, moist handshake, and it may be soaking undergarments or bedclothes. Severe muscular weakness and wasting may be present, associated with excessive katabolism of muscular tissue and creatinuria. Myasthenia gravis, acute bulbar palsy, and progressive muscular atrophy may be simulated.

Gastro-intestinal.—The paradox of an insatiable and voracious appetite with progressive loss of weight is a source of wonder and concern to patient and relatives. The explanation is a raised metabolic rate. Excessive thirst is an effort to compensate for loss of fluid by profuse perspiration. Attacks of dyspepsia occur, sometimes with vomiting, and this may be due to hepatic

disturbance, but achlorhydria and hypochlorhydria are not infrequent. Achlorhydria, or vegetative nervous irritability, may explain attacks of diarrhoea, which if severe or inadequately controlled may result in dehydration.

Ocular signs.—Exophthalmos is present in 70 per cent. of cases, and may be slight or severe, often regardless of the degree of severity of the thyrotoxicosis. Although characteristically bilateral, one eye may be affected before the other, or in lesser degree, presumably because of anatomical differences. The exophthalmos is not usually associated with dilatation of the pupil. It is interesting to note that pituitary thyrotrophin will cause exophthalmos, experimentally, even after paralysis of the cervical sympathetic, or after thyroidectomy. The latter fact explains why exophthalmos sometimes persists after an adequate thyroidectomy. Apart from true exophthalmos, this condition may be simulated, or appear intensified, by upper lid retraction, which may be unilateral or bilateral. In this condition the upper lid only reaches to the upper periphery of the cornea, or even not so far, whereas in exophthalmos white sclerotic may be seen between the cornea and the lower eyelid. Mild degrees of lid retraction, with or without slight exophthalmos, may be indicated by a glint in the eye, or a restless coquettish look. Other ocular signs associated with classical names are of little practical significance.

Exophthalmic ophthalmoplegia (Brain) is a condition of considerable severity occurring in middle-aged people in association with a relatively mild hyperthyroidism, or with hypothyroidism following thyroidectomy. The disorder is usually unilateral, or one eye is more affected than the other, and there is paralysis of ocular movement in one plane. Although it appears to be a distinct clinical entity, the ocular muscles show cedematous swelling and degeneration as in exophthalmic goitre, and a thyrotrophic stimulus has been postulated for both conditions.

Thyroid gland.—This is almost invariably enlarged, although the degree is by no means proportional to that of the thyrotoxicosis. The enlargement usually affects both lobes, and not infrequently the isthmus. The swellings are smooth and roughly symmetrical, but one lobe may be larger than another. Small degrees of enlargement may be missed unless the proper technique of palpation is observed. The thumb should compress the site of one lobe of the thyroid against the trachea, and the opposite lobe then becomes palpable to the thumb or fingers of the other hand. This procedure is best carried out with the patient lying flat without a pillow. A systolic bruit over the thyroid may be heard on auscultation.

Metabolism.—The thyroid gland controls metabolism, and the increased basal metabolic rate in thyrotoxicosis is a fundamental feature. Modern mechanical apparatus which records oxygen absorption permits the estimation in 10 minutes, and is a valuable arithmetical method of measuring the severity of the disease and its subsequent progress. There is a negative nitrogen balance, and excessive creatinuria indicates a pathological breakdown of muscle tissue. The fat depots of the body tend to disappear, and the serum cholesterol is low, *e.g.* 100 compared with normal 180.

The liver is depleted of glycogen, and transient or persistent glycosuria may appear. This rarely indicates true diabetes mellitus, which is not more common among thyrotoxic patients than among the rest of the population. Nevertheless, thyroxine is antagonistic to insulin. In thyrotoxic glycosuria,

the resting blood sugar level is normal, but following 50 grams of glucose there is a high and prolonged blood sugar curve. In the absence of gastrointestinal symptoms, or partial starvation, ketosis does not occur. There may be a negative calcium balance and, although the serum calcium is not raised, as in hyperparathyroidism, the renal excretion of calcium is not infrequently excessive. There results a decalcification of the bones, which rarely may reach a severe degree. The negative calcium balance is not apparently proportional to the basal metabolic rate, and is not always cured by thyroidectomy, even when the latter is otherwise successful. There is a negative iodine balance, with a raised blood iodine and increased urinary excretion of iodine. Unless iodine is given, the thyroid gland in thyrotoxicosis contains appreciably less iodine than the normal gland, because thyroxine is rapidly secreted and not stored.

Other features.—Relative impotence may be present in the male, and amenorrhœa or scanty menstruation is common in females. Pigmentation is rare, and, if present, is usually confined to the orbital regions, but occasionally diffuse pigmentation is met with. Premature whitening of the hair sometimes occurs. No characteristic blood changes are met with, but a lymphocytosis may be present. Dyspepsia and diarrhœa may be troublesome features. Occasionally abdominal pain may be severe enough to simulate an acute abdomen, and on laparotomy acute congestion of the pancreas has been observed. Crises are an alarming feature of thyrotoxicosis, sometimes precipitated by infection, or occurring in the first few days after thyroidectomy, but often without obvious cause. There is an acute exacerbation of the condition, with manifestations predominantly cardiac, cerebral, or gastro-intestinal, and patients may die unless the condition is promptly recognised and treated. Cerebral forms of crises are particularly dangerous, and are manifested by acute excitement and irritability, acute mania, delusions and hallucinations. There is also a comatose form in which the patient is apparently unconscious, or if barely conscious, is unable to speak or move.

Diagnosis.—When the classical features of tachycardia, exophthalmos, enlarged thyroid, tremor of the hands, and loss of weight are present the diagnosis usually offers no difficulty, and a raised basal metabolic rate is confirmatory evidence.

"Masked" forms of hyperthyroidism, or "*formes frustes*," in which the presenting feature appears to indicate some other disease, may offer difficulty, but awareness of the possibility of hyperthyroidism usually prevents a mistaken diagnosis. Thus, cardiologists are always on the look out for a possible thyroid basis in cases of auricular fibrillation, and it would seem that the latter may occur in paroxysmal form before the clinical picture of hyperthyroidism is well developed, while occasionally fibrillation may supervene some years after the disease is apparently arrested.

Loss of weight, sweating, and rapid pulse may suggest pulmonary tuberculosis; or wasting combined with glycosuria give rise to a diagnosis of diabetes mellitus. Glycosuria may be found in thyrotoxicosis without diabetes being present. It is often intermittent and independent of diet. A carbohydrate tolerance curve may give high blood sugar values, and return slowly to normal, but the fasting blood sugar will not be raised unless true diabetes mellitus is present as a complication. The muscular wasting and

weakness of hyperthyroidism may simulate the myopathies, or myasthenia gravis. The latter is an extremely rare complication of thyrotoxicosis, and is differentiated by the selectivity for groups of muscles and the response to prostigmine. Some patients are treated for an associated neurasthenia before the thyrotoxicosis is recognised. An overactive sympathetic nervous system at the climacteric may produce many features simulating thyrotoxicosis, but only a small proportion of such patients have a true thyrotoxicosis. Neuro-circulatory asthenia may simulate hyperthyroidism, and the thyroid gland is often somewhat enlarged, but in the former the tachycardia is more dependent upon emotion and change of position, and the pulse rate at rest or when sleeping is usually not raised.

Course and Prognosis.—The natural course of the disease, in the absence of treatment, is progressively downhill, but waves of remission and exacerbation occur. Nevertheless, some patients spontaneously recover, or even become myxoedematous. The chief dangers are cardiac failure, intercurrent infection, and mental disorder. Radical treatment produces a fundamental change for the better, but residual characteristics of thyrotoxicosis are met with. Although pathological upper lid retraction usually disappears, some degree of exophthalmos not infrequently persists.

Treatment.—It should be noted that the treatment of exophthalmic goitre is always medical, even although more often than not an essential part of treatment is surgical removal, or radiological destruction, of the greater part of the hyperactive thyroid gland. Some patients respond to medical treatment alone, and in early or mild cases this should always be given a fair trial. Rest and quiet, together with sedatives, are obvious indications. Quinine hydrobromide is sometimes used, in dosage of 10 gr. t.d.s., the thyrotoxic patient having an increased tolerance for this drug. Phenobarbitonum, gr. $\frac{1}{4}$ to $\frac{1}{2}$ t.d.s is also a well tolerated sedative. It is wise not to neglect some form of psychotherapy, especially if anxiety symptoms predominate.

As to the use of iodine medically over prolonged periods, it is usually held that iodine should be restricted to pre-operative use, since the patient becomes refractory or even worse after some two weeks. In my experience, however, small doses of iodine, such as 3 minims of Lugol's iodine once daily, may be continued for months or years with benefit. It is not curative, but it appears to enable the disease to run its course at a lower level of thyrotoxicosis and has a favourable influence on all the symptoms. The gland itself, however, may become larger and more tense as the vesicles become distended with colloid. Lugol's iodine is usually taken in an ounce or two of milk after a meal. It may be replaced by di-iodotyrosine tablets, 10 mg. or more daily. Simple tachycardia is uninfluenced by digitalis, which should only be employed when the condition is complicated by auricular fibrillation or cardiac failure (see Heart section). Insulin, testosterone and adrenal cortical extract have all been advocated, and are of some limited value, but do not constitute essential therapy.

More recently thiourea and thiouracil have been found by Astwood, Himsworth, and others, to produce a lowering of the basal metabolic rate, and of the pulse rate, a rise in the sub-normal blood cholesterol values usually found in thyrotoxicosis, an increase in weight, and a general clinical improvement. These effects are usually seen after some 2 weeks of treatment, and

good results have been maintained over long periods. Thiourea produces a mal-odour of the breath, and it is preferable to use thiouracil. The initial dose is 600 to 1000 mg. a day in 100 mg. tablets, for 2 weeks, and then 200 mg. or less daily. The smallest effective dose should be employed, as larger doses, and sometimes even small doses, in sensitive people, may produce agranulocytosis (occasionally fatal), leucopenia, thrombopenia, fever, dermatitis, arthralgia, jaundice, generalised lymphadenopathy and splenomegaly. For this reason, treatment should, where possible, be controlled by close observation, periodic estimations of the basal metabolism, blood cholesterol, and white cell counts. Toxic symptoms may occur in the first few weeks, but occasionally do not manifest themselves until after several months' therapy, even when the dose of thiouracil has been reduced to 100 mg. daily. Malaise, sore throat and pyrexia suggest agranulocytosis. Even in the absence of toxic symptoms, however, an attempt should be made to cease thiouracil therapy after some months, if the basal metabolism is normal and the clinical condition is good. Some 50 per cent. of patients will continue to remain well, but observations over a period of years have not yet been made. Some patients fail to respond to thiouracil, and this may be due to previous medication with iodine, but if iodine administration is stopped, most patients respond after a few weeks. During thiouracil administration, however, iodine appears to reinforce the effects. Although thiouracil diminishes lid retraction, it has less influence on exophthalmos, and may be without effect in this condition. In a few cases the degree of exophthalmos increases. Similarly, the size of the thyroid gland may remain the same, may diminish slightly, or may increase under thiouracil therapy. Thiouracil should not be used in those cases where pressure symptoms are present or likely to result. Thiouracil appears to act by preventing the synthesis of thyroxine, and a secondary effect is secretion of pituitary thyrotrophic hormone, resulting in hyperplasia of the thyroid gland, without, however, an accompanying output of thyroxine. Some surgeons use thiouracil alone, or together with iodine, in the preoperative preparation of patients with severe thyrotoxicosis. It is necessary to wait 2 or more weeks before the optimum condition is arrived at.

Sepsis frequently produces an exacerbation of exophthalmic goitre, and removal of septic foci an amelioration. Nevertheless, tonsillectomy or even dental extraction may be followed by a severe crisis endangering the life of the patient, and when the disease is of any severity it is more prudent to resort to radiation or thyroidectomy before removing the septic foci. Pregnancy tends to aggravate the malady, although temporary benefit is sometimes observed, and the incidence of miscarriage, premature and stillbirths, is high. Thyroid radiation or thyroidectomy within the first few months is the best treatment.

Thyroid crises are treated by the intravenous injection of 100 minims of Lugol's iodine in 20 c.c. saline, or in a litre of glucose-saline given slowly by the intravenous drip method, and oxygen. If the crisis occurs after thyroidectomy, and response to the above measures is not good, some surgeons open the neck incision.

Surgical Treatment.—When medical treatment has failed to control the disease, or in those cases in which the malady is advanced when first seen, and still more so when auricular fibrillation has supervened, there should be no undue delay before resorting to surgery. The worse the cardiac condition,

the more urgent the need. It should be remembered that total thyroidectomy is sometimes advocated for cardiac insufficiency even in the absence of exophthalmic goitre; and that auricular fibrillation or cardiac failure associated with the disease tends to be refractory to digitalis or quinidine unless thyroidectomy is performed. The use of pre-operative iodine and the improvement in anaesthesia and surgical technique have reduced the mortality considerably, and thiouracil is a further aid in bringing patients to operation in the optimum condition.

Lugol's iodine is given in doses of 10 minims t.d.s. for 10 days before operation. Bromethol (avertin), 0.1 gram per kilo weight, is administered per rectum, and may be preceded in nervous patients by the injection of gr. $\frac{1}{2}$ morphine. The patient is usually drowsy or asleep after 30 minutes and can then be taken to the operating theatre. Gas and oxygen, but no ether, supplement the anaesthesia, and many surgeons also use local infiltration with 0.5 per cent. procaine hydrochloride (novocaine). After operation, restlessness is controlled by sedatives by the mouth or per rectum. Morphine should be used sparingly, as cyanosis is best avoided. In the presence of cyanosis, or even merely with exacerbation of general symptoms, an oxygen tent or room is of great value. The Lugol's iodine is continued as before operation, initially in rectal saline, and after a week the dose is gradually reduced to 5 minims daily, which is continued for 3 months. This is thought to prevent recurrence of exophthalmic goitre, but large doses of iodine may encourage the onset of myxedema if the thyroidectomy has been extensive. The pulse rate and temperature are usually raised for some days after operation, after which there is a gradual return to normal. Auricular fibrillation may appear for the first time after operation, but frequently disappears spontaneously after a few days. If not, quinidine sulphate is employed, 3 grains on the first day, increasing up to 3 grains five times a day. If no effect after 40 grains, digitalis is given. If fibrillation is terminated by quinidine, the rhythm will frequently remain regular on discarding the quinidine (see also Cardiac Section). It is advisable for the patient to endeavour to lead a quiet, untroubled life for some months after operation. Some 60 per cent. of patients are cured, and the remainder improved in varying degree.

Radiation.—Deep radiation, carried out with proper technique, gives results comparable to those of good surgery in a good proportion of cases. The beneficial results may not be obvious for several months, and this interval must elapse before a second course of radiation is permitted, otherwise myxedema may result.

Treatment by radium surface application or the insertion of radon seeds is not generally considered to be as efficacious, although advocated by some.

TOXIC ADENOMA

Synonyms.—Toxic adenomatous goitre; Thyrotoxic Nodular Goitre; Secondary Thyrotoxicosis.

Definition.—Hyperthyroidism associated with, and usually superimposed upon, a nodular goitre.

Aetiology.—Thyrotoxic symptoms occur in some 15 per cent. of nodular goitres. The cause is usually unknown, but occasionally iodine appears to provoke thyrotoxicosis in a quiescent gland.

Pathology.—Plummer's term, Toxic Adenoma, which is in general use, might be thought to indicate a single adenoma, but only rarely is this the case. More commonly multiple adenomas are found throughout the glands, and, apart from these, other areas of the gland may show a hyperplasia, indistinguishable from that found in exophthalmic goitre, as well as areas of colloid vesicles. In fact the histological picture is a variable one, and some pathologists refuse to make any clear distinction between toxic adenoma and exophthalmic goitre. It is certainly true that general hyperplasia of other endocrine glands, *e.g.* adrenal cortex, may be accompanied by the formation of multiple adenomas. Occasionally thyrotoxicosis supervenes on a smooth diffuse colloid goitre.

Symptoms.—Thyrotoxic symptoms develop in a patient who has had a symptomless nodular goitre for some years, and usually without obvious cause. It is, however, not always possible to say if a goitre has been present before thyrotoxic symptoms develop.

Plummer has postulated that in true adenoma there is a simple hyperthyroidism as distinct from exophthalmic goitre where there is also a qualitative difference in the secretion of the hyperplastic gland. Although this theory has not been substantiated, it does draw attention to certain differences in the two clinical conditions. Thus in toxic adenoma, upper lid retraction is usually absent and exophthalmos slight; nervous excitability is less intense, associated anxiety neurosis uncommon, and psychosis extremely rare; hyperthyroid crises are hardly met with. The brunt of the disease falls on the cardio-vascular system, and auricular fibrillation is not infrequent, but this may be associated with the greater age incidence as the majority of patients are over 40. Occasionally progressive loss of weight is the presenting feature. Although certain clinical differences can be discerned between exophthalmic goitre and toxic adenoma, the two conditions have much more in common than in difference, and the greater part of what has been written about exophthalmic goitre (which see) applies to toxic adenoma as well.

Prognosis.—Inadequately treated, the condition deteriorates rapidly and cardiac failure results. The response to thyroidectomy is excellent and the percentage of recurrence is less than one per cent.

Treatment.—Similar principles apply as in exophthalmic goitre, but thyroidectomy is the optimum treatment and should be undertaken without undue delay. Paradoxical as it may seem, the worse the condition of the heart, the greater the urge for thyroidectomy, as medical measures are usually of no avail. Recently, thiouracil has been shown to be of use in toxic adenoma, but the response is much slower and usually less satisfactory than in exophthalmic goitre. It should not be used when pressure symptoms are present or probable, as an initial enlargement of the goitre may follow thiouracil treatment. Iodine as a pre-operative measure is effective in the majority of cases, although to a less extent than in exophthalmic goitre.

MYXŒDEMA

Definition.—A primary condition of hypothyroidism, associated with low basal metabolism, and manifested by sensitivity to cold, mental hebetude, loss of hair, and mucoid infiltration of the skin and subcutaneous tissue. It

does not include hypothyroidism secondary to pituitary hypofunction, as in Simmonds's cachexia.

Ætiology.—Myxœdema usually occurs sporadically and without obvious cause, although there is occasionally a history of preceding infection. It is more frequent in women than men, in the ratio of 8 to 1, and is most common in middle age. Perhaps the condition in women is comparable to the cessation of ovarian function, which also is met with in the fourth decade. The disease, however, may have its onset in old age, or even in childhood—when it is known as juvenile myxœdema. There would also appear to be a constitutional predisposition, as several cases in the same family may be met with. Myxœdema may follow partial thyroidectomy for thyrotoxicosis, or complete thyroidectomy for non-thyroid cardiac disease, the term *cachexia strumipriva* sometimes being given to post-operative myxœdema. Apart from operation or excessive radiation, myxœdema may spontaneously follow chronic thyrotoxicosis. Another group of myxœdematous cases occurs endemically and usually with goitre, the ætiology being a relative or absolute iodine deficiency.

Pathology.—The thyroid is atrophic, and the secreting epithelium is largely replaced by fibrous tissue. The skin and subcutaneous tissue are infiltrated with a mucoid-like material, which was wrongly thought to be mucin, and hence the name myxœdema. There is an abnormal accumulation of extra-cellular and extra-vascular protein, the osmotic pressure of which leads to a transfer of saline from plasma to interstitial tissues. The mucoid infiltration may be widespread and implicate the nasal, pharyngeal, buccal and auditory mucous membrane, salivary glands, the larynx, and the œsophagus. The kidneys are sometimes extensively involved, and there may be deposits in the vulvo-vaginal region. The heart and coronary vessels not infrequently show atheromatous changes, with some cardiac dilatation, but contrary to general belief, actual mucoid infiltration is a rarity.

Symptoms.—The onset is usually insidious, and at least half the patients have had the disease for some years before it is recognised. The general condition is comparable to hibernation, all the physical, metabolic and mental processes being sluggish and reduced much below the normal.

Integument.—The facies is pale and puffy, with baggy eyelids and a characteristic malar flush. There is thinning of the outer half of the eyebrows, and the hair of the head is dry and lustreless and falls out, sometimes with resulting patchy alopecia. The skin is dry and rough, and gives a swollen œdematous appearance, especially in certain regions, *e.g.* face, neck, supraclavicular areas, hands, legs and feet; but there is no pitting on pressure. In contrast to hyperthyroidism, obvious sweating is minimal or absent.

Cardio-vascular.—The pulse rate is characteristically slow, *e.g.* 50, but there may be tachycardia with cardiac insufficiency. The blood pressure may be raised but not necessarily so. Angina sometimes occurs. Radiography usually shows enlargement of the heart, and the electrocardiogram a flattened or inverted T wave, etc. (see Cardiac Section).

Mental changes.—Apart from the psychoses, especially melancholia, which may complicate advanced or chronic cases, there are characteristic abnormalities of behaviour. The intellectual processes appear dimmed, and memory is poor. There is a noticeable latent period before questions are

answered, and speech is slow, thick, indistinct and rather toneless. The whole attitude is apathetic and lethargic, with a tendency to somnolence.

Metabolism.—The basal metabolic rate is usually of the order of -10 , the temperature is subnormal, and the patient hypersensitive to cold, being especially intolerant of the winter months. There is an almost constant hypercholesterolemia, e.g. value of 400 mg. per cent., compared with a normal of 180; the cause of this is uncertain. The fasting blood sugar may be normal or slightly below normal, and there is apparently an increased carbohydrate tolerance in some patients. The injection of 4 units of insulin intravenously is followed by a slower rate of fall of blood sugar than occurs in normal individuals, although the subsequent rise in blood sugar may appear retarded. Occasionally diabetes mellitus occurs as a complication of myxœdema, the pancreatic islets, as well as the thyroid, being atrophic.

Blood.—There are three types of anæmia found in myxœdema: (1) Hypochromic low colour index anæmia. This variety responds to iron. It differs from other iron deficiency anæmias, however, in the absence of microcytosis. (2) Hyperchromic megalocytic high colour index anæmia. This responds to liver, and is comparable to pernicious anæmia. (3) Simple hyperchromic macrocytic high colour index anæmia. It differs from Addisonian anæmia in the absence of megalocytosis and failure to respond to liver. Neither does it respond to iron, but thyroid has a specific effect, although a gradual one. The three types may be associated with achlorhydria, which is not uncommon, but type (3) is a specific thyroid deficiency anæmia. Either of the first two types may, on treatment with iron or liver respectively, change into the last type (simple hyperchromic). It is generally assumed that thyroid is a direct hæmopoietic agent essential for maturation of red cells, but the partial atrophy of the erythron in hypothyroidism may be an adaptation to the diminished need of the tissues for oxygen.

Other features.—Constipation is common, in contrast to the diarrhœa of thyrotoxicosis. Similarly, appetite and thirst are diminished. Deposits of mucoid material may impair hearing, smell, taste and swallowing. There may be amenorrhœa or menorrhagia, and in the male relative or absolute impotence is not infrequent. Vague generalised pains may be a feature, and some recognise a subthyroid form of chronic rheumatism.

Diagnosis.—Even though well-developed myxœdema presents a characteristic clinical picture, it is perhaps the most frequently missed endocrine disorder, and this is certainly true of the early or slight cases. The best method of avoiding this is to constantly bear in mind the existence of the disorder, especially when dealing with menopausal multipara. Sluggish mental response, with thick, dry skin and loss of hair, failure of memory, and sensitivity to cold are characteristic.

Many patients will first be seen by the psychiatrist, although the disease must have been present for some time. Others will present themselves to the gynæcologist on account of menorrhagia. Again, the appearance of the patient may lead to the diagnosis of anæmia, confirmed by blood examination, but the other features should not be missed. The pale, puffy face with baggy eyes also resembles the facies of parenchymatous nephritis, and albuminuria may complicate myxœdema if the kidneys are involved in the mucoid infiltration; a further resemblance between the two conditions is the high blood cholesterol. Myxœdema may be difficult to differentiate from

hypothyroid features in Simmonds's cachexia (which see), both having a low B.M.R. and sensitivity to cold. In the latter condition, however, mucoid infiltration of the skin is rare, the skin being thin and wrinkled, and the patient has lost much weight. In pituitary hypothyroidism, thyrotrophic hormone will raise the metabolism to normal, but it has no such effect in myxœdema, the atrophied thyroid gland being unable to respond.

Localised myxœdema may paradoxically be a complication of hyperthyroidism, usually in a recurrent or post-operative phase. The B.M.R. may have changed from above to below normal, but is sometimes still raised. Thick œdematous plaques appear on the front of the shins, or the whole leg may be thickened. The overlying skin is often wrinkled and hairy, and the skin may itch or burn. Nodular lesions may also involve the face, arms, back or scrotum. The pathogenesis of localised myxœdema is uncertain, for the response to thyroid is poor.

Course and Prognosis.—In the absence of specific treatment the course is slowly but progressively downhill, and many patients end in the asylum. The response to treatment, however, is usually excellent though by no means necessarily so if a psychosis has already developed.

Treatment.—The specific treatment in myxœdema is thyroid. The drug is best given in the form of thyroideum, B.P. The maintenance dose for the average patient is about 3 grains daily. It is, however, prudent to commence with smaller doses, *e.g.* 1 gr., especially because of the extra strain that may be thrown on the heart by the increase in metabolism and the rate of circulation. A heart that was previously adequate may be unable to meet the extra demand, and cardiac failure or even angina may supervene if the initial dosage is too large. In the long run, however, thyroid in appropriate dosage has a beneficial influence on the cardio-vascular system. If an untreated myxœdematous patient is first seen with some cardiac insufficiency and a rapid pulse (in contrast with the usual bradycardia), there may be hesitation to give thyroid; but in small and gradually increasing dosage the drug has a beneficial if paradoxical effect, the cardiac rate diminishing as the heart and coronary circulation improve. With the more usual bradycardia, thyroid has the effect of increasing the pulse rate, and should this rise above 76 the dose of thyroid should be reduced. More exact criteria of dosage may be obtained by estimations of the basal metabolic rate or the blood cholesterol. It is useful to remember that thyroid, even if administered intravenously as a single dose of thyroxine, requires 24 to 48 hours to begin to act, has its maximum effect at the end of a week, and continues to act for several weeks. There is therefore no point in giving thyroid more often than once daily, and a cumulative effect may be guarded against by missing one week in four. Thyroxine has no advantage over the dried gland, and its intravenous administration is not without danger as the initial reaction may be alarming, *e.g.* nausea, vomiting, angina, pyrexia, aching muscles, loss of hair and peeling skin.

Hypochromic anæmia is treated with iron; simple hyperchromic anæmia with thyroid; Addisonian anæmia with liver. Whatever the appropriate indication, thyroid will not be withheld except for scientific investigation. If exact hæmopoietic investigation is not available, most anæmias met with in myxœdema will respond to iron and thyroid, true Addisonian anæmia being very rare.

CRETINISM

Definition.—This is a condition of hypothyroidism beginning in foetal life. In contrast, childhood myxœdema is superimposed on a normal infancy. The disorder may occur endemically or, more rarely, sporadically.

Ætiology.—The endemic form occurs in goitrous areas, the mother usually having a goitre. Iodine deficiency of the soil and water, and other theories are discussed in the Goitre section. No cause for the sporadic form is known. The sex incidence in both varieties is about equal.

Pathology.—In the endemic form, the goitre is usually the nodular adenomatous variety (see Goitre). In the case of sporadic cretinism, a goitre is rare, the thyroid being atrophic, with flattened irregular epithelial cells, small alveoli, and connective tissue overgrowth.

Symptoms.—The untreated cretin is mentally deficient, apathetic and somnolent, and tends to lead a vegetative existence. All the processes and stepping stones of childhood development are retarded, the fontanelles remain open for years, centres of ossification appear late, and the epiphyses remain ununited for long periods. Growth, however, is always deficient and cretinism is a variety of dwarfism. The facies is characteristic, being pale and pasty, and having a thick skin, wrinkled forehead, a broad nose with depressed bridge and big nostrils, and thick lips separated by a protruding enlarged fissured tongue. The hair on the head is dry and scanty, and the eyebrows and eyelashes frequently deficient. The body is characterised by a protruding, pendulous abdomen, with umbilical hernia, supraclavicular pads of fats, and some degree of scoliosis and lordosis. The hands are spatulate, with square finger tips, and the limbs lack muscular tone. Deafness is not infrequent, and speech is often impaired. Genital development is always retarded, and ultimate sexual maturity a rarity. As in the case of myxœdema, there is a low basal metabolic rate, subnormal temperature, sensitivity to cold and constipation.

Diagnosis.—To those who have seen the characteristic appearance, the diagnosis of cretinism rarely offers difficulty. In contrast, a Mongol has mongoloid eyes, with epicentric folds, a good skin and complexion, fine but profuse hair, and a restless, bright manner.

Course and Prognosis.—If untreated, cretins remain semi-idiot and incapable of self-sufficiency. Intercurrent infection in childhood or adolescence is a common termination. Normality may be achieved by treatment from infancy, but delayed therapy results in some irreversible changes. Further, mental deterioration may occasionally supervene in later life on approximate normality, which has been maintained by adequate thyroid treatment.

Treatment.—Prophylactic treatment in endemic areas consists of small doses of iodine (see Goitre).

Treatment of the individual patient is specific, namely thyroid. One to three grains daily of thyroideum, B.P., or more, may be required, as judged by the general effects and the cardiac rate. If given in infancy or early childhood, an approximation to normal may be attained, but sometimes a harmless, apathetic idiot is merely changed into a mischievous, truculent semi-idiot.

GOITRE

Definition.—A goitre is a pathological enlargement of the thyroid gland, which may be endemic or sporadic, symptomless or associated with hyperthyroidism or hypothyroidism. The contour of the gland may be smooth or nodular.

Ætiology.—Endemic goitre occurs in many regions throughout the world, including certain areas in this country, *e.g.* Derbyshire and Somerset. In Switzerland, where earlier investigations were undertaken, one factor found to be common to goitrous regions was a deficiency of iodine in the water and soil. This is not always the case in other parts of the world, and goitrogenic agents in an infected water supply have been implicated, although the deleterious effect may be obviated if the iodine content of the water is higher. Vitamin deficiency and a preponderance of calcium over iodine are other possible factors.

The ætiology of sporadic goitre is obscure. Apart from a possible relative iodine deficiency, a familial predisposition is sometimes apparent. The increased demands of the body for thyroxine at puberty may be indicated by a transient physiological thyroid enlargement, but this sometimes persists as a puberty goitre. Endemic goitre is usually obvious in childhood, and its peak incidence is at puberty. This is also true of sporadic goitre, which may however be met with at all ages. The sex incidence of goitre is about equal in childhood, but, after puberty, females are more often affected than males—about 8 to 1.

Pathology.—The smooth diffuse goitres may be divided into the parenchymatous and the colloid, although both histological features are not infrequently present in the same gland. The parenchymatous goitres often show degenerative changes in the epithelial cells, and areas of fibrosis. The colloid goitres contain low cuboidal epithelium lining vesicles, filled with colloid. Nodular goitres usually contain multiple capsulated adenomas, which may show cystic or hæmorrhagic change. Occasionally there is a single adenoma, which may be of colloid type or of parenchymatous type. In the latter case, it is thought by some to arise from solid masses of embryonic cells that may be seen in normal glands, and for this reason is termed "Foetal adenoma."

The above pathological changes occur both in endemic and sporadic goitres.

Symptoms.—When goitre is associated with hyperthyroidism, the symptoms may be those either of Graves's disease or of secondary thyrotoxicosis (which see). When associated with hypothyroidism, the clinical picture is that of cretinism or myxœdema.

In all varieties of goitre, including those which are endocrinologically inactive, pressure symptoms may be the major manifestations, especially so in the case of nodular goitres, and when goitres are low down in the neck or behind the sternum (intra-thoracic), pressure symptoms may be the only indication apart from that given by radiological examination. Pressure on the trachea may produce difficulty in breathing, irritating cough, alteration in voice, and stridor. For mechanical reasons, the dyspnoea is worse on lying down, and attacks of dyspnoea with cyanosis may be fatal. The voice is also affected by paralysis of the recurrent laryngeal nerve, this, however, being

rarely bilateral. Pressure on veins may produce dilatation of those of the head and neck, with cyanosis, and in the case of intrathoracic goitre, dilated veins may be evident over the chest. Oesophageal pressure and resulting dysphagia are rare, as also are bradycardia due to vagus involvement, and mydriasis and sweating from cervical sympathetic stimulation.

Complications.—Malignant change is said to supervene in 1.6 per cent. of all goitres, and in 2.7 per cent. of nodular goitres. It is usually only after some years that malignancy develops, and clinical indications are a rapid increase in size and hardness of the goitre over a period of weeks or months, the development or increase of pressure symptoms, especially dysphagia, and lack of mobility in relation to the adjacent structures, *e.g.* the trachea. Metastases in the lungs, liver, and bones, may unfortunately be the first recognised indication in some patients. The commonest age of onset of malignant changes is from 50 to 70, and such a change is nearly always superimposed on a pre-existing goitre. In cases in which malignant changes supervene, 35 per cent. are correctly diagnosed before operation, 30 per cent. at operation, and the remainder only on histological examination.

Diagnosis.—This is usually obvious on inspection. Intra-thoracic goitre may be simulated by thymus or mediastinal tumours. Sometimes auricular fibrillation in a middle-aged or elderly person may draw attention to a small pre-existing goitre which has been symptomless for years. Pressure symptoms on the trachea may simulate asthma, perhaps with the complication of bronchitis, and some of these cases are not diagnosed for years.

Course.—A goitre may remain symptomless and innocent throughout life, but at any time toxic symptoms of hyperthyroidism or hypothyroidism may become manifest.

Treatment.—In Switzerland the addition of iodine to all salt sold, 1 part in 100,000, has enormously reduced the incidence of endemic goitre. In areas of endemic goitre in France, 1 minim of Lugol's iodine daily, has been employed, and in America iodised salt, 1:10,000, both with varying and on the whole satisfactory results. As might have been anticipated, the results are best if iodine has been administered to the mother throughout the pregnancy, but even when first given in childhood, the incidence of goitre is considerably reduced. It is to be pointed out that in the case of symptomless endemic goitre, especially of the nodular variety, the use of iodine is not free from the danger of inducing thyrotoxicosis. This is also true in the case of sporadic goitre, although the writer believes that in simple diffuse goitre the risk is insignificant. At the same time, it is to be remembered that some symptomless endemic goitres become hyperactive apart from any treatment. Marine advocates, as an alternative to iodine, the use of thyroideum, B.P. 1 to 2 gr. daily, for simple sporadic goitre. This method of treatment, while logical and safe, is rarely curative.

Pressure symptoms or toxic manifestations call for early thyroidectomy, which is also justifiably undertaken for cosmetic reasons. Malignant goitre, if inoperable, is treated by radiation or insertion of radium needles or radon seeds.

DISEASES OF THE PARATHYROID GLANDS

The parathyroids are four in number, and are usually situated symmetrically in the posterior aspect of the thyroid gland. They secrete a hormone, parathormone, which gives protein colour reactions, is soluble in water and 80 per cent. alcohol, but insoluble in ether or acetone. The chief function of the glands is the regulation of calcium and phosphorus metabolism. Excess of the hormone leads to the clinical entity of osteitis fibrosa diffusa, and deficiency to tetany.

HYPERPARATHYROIDISM

Synonyms.—Generalised Osteitis Fibrosa Cystica; Osteitis Fibrosa Diffusa.

Definition.—A disease due to the excessive secretion of parathormone, and manifested clinically by hypercalcaemia, negative calcium balance, muscular atony, weakness and wasting, and decalcification of bones resulting in deformities and fractures.

Ætiology.—The disease, which is rare, is due to a neoplasm or hyperplasia of the parathyroid glands. The latter may be secondary to a pituitary stimulus, but parathyrotrophic hormone has not been demonstrated in the blood. The malady affects women twice as frequently as men. The average age incidence is about 40, but it also occurs in childhood and old age.

Pathology.—A circumscribed adenoma of one parathyroid gland is the commonest lesion, the remaining three glands being normal or hypoplastic, but two adenomas have been found at operation. There may, however, be general hypertrophy and hyperplasia of all glands, which is usually obvious to the naked eye, and may even be of extreme degree, e.g. one weighing 5 grams compared with a normal of 60 mg. Such changes are comparable to the hyperplasia, with or without adenomatous formation, in the thyroid gland of thyrotoxicosis. The parathyroid cells are greatly enlarged, and the cytoplasm highly vacuolated. The essential skeletal changes are softening, replacement of bone marrow by fibrous tissue, rarefaction of the cortex, and the presence of numerous osteoclasts and osteoblasts, with osteoclastic giant cells and cyst formation. Deposits of calcium as fine granules may be present in all the viscera, especially the kidneys and lungs. Occasionally hyperplasia of the parathyroid glands is secondary to chronic renal insufficiency.

Symptoms.—These are all the direct or indirect result of excessive calcium mobilisation and excretion. The long bones may be bent and deformed, with perhaps osteoclastic tumours, and in some cases pathological fractures. The vertebrae are compressed, and not infrequently height is diminished by several inches. Osteoclastic swellings may deform the jaw. The shape of the skull is rarely distorted clinically. The bones and osteoclastomatous swellings are often tender, especially on pressure. The teeth are not decalcified. The muscles show atony, fatigueability, and atrophy.

Gastro-intestinal symptoms are nausea, vomiting, constipation, abdominal pains and cramps. Polyuria and polydipsia are associated with the increased calcium excretion. Urinary symptoms are common. The calcium may be deposited diffusely, giving rise to the presence of chronic nephritis and renal insufficiency, or even multiple renal calculi, the latter consisting chiefly of calcium and phosphorus. Renal colic and pyelocystitis are complications. In some patients the presenting symptoms are those of renal calculus, without any indication of hyperparathyroidism. In clinics where all such cases undergo investigation of calcium metabolism a number (1 to 5 per cent.) have been shown to be due to primary hyperparathyroidism. It is also important to remember that bone changes may be relatively slight and in acute cases undetectable radiographically, although the serum calcium is raised. Acute hyperparathyroidism may present itself as weakness, wasting, drowsiness or semi-coma, nausea or vomiting, and cardiac failure. The condition can be produced experimentally by the injection of parathormone.

Metabolic changes.—The calcium and phosphorus are mobilised from the bones, and excreted in excess in the urine and to a much less extent in the faeces. The serum calcium is usually raised, e.g. 15 mg. per cent. (normal 10 mg.), and the plasma phosphorus is diminished, e.g. 2 mg. per cent. (normal 3.5 mg.). A normal serum calcium does not necessarily exclude the disorder, providing that the serum phosphorus is persistently low, and the calcium balance negative. In the presence of advanced renal disease, however, there may be phosphorus retention and a raised serum phosphorus. The plasma phosphatase is raised, e.g. 13 units compared with a normal of 2 units, and is a measure of osteoclastic activity. In the absence of recognisable bone changes, the phosphatase may not be raised.

Diagnosis.—Radiography shows generalised osteoporosis, with granular mottling in the skull, but an absence of demonstrable radiographic bone changes in itself does not exclude the diagnosis. Multiple calcium deposits, minute and diffusely scattered or large enough to be called calculi, may be shown in skiagrams of the kidneys, and sometimes of the lungs. If estimations of serum calcium, phosphorus and phosphatase are inconclusive, the intake and output of calcium must be measured over a few days to determine if a negative calcium balance is present.

When urinary symptoms are prominent, the underlying primary hyperparathyroidism may be unsuspected in the absence of metabolic investigation. Rarely, hyperparathyroidism of severe degree occurs secondary to chronic nephritis of long standing, and, in such patients, although the total urinary and fecal calcium excretion is above normal, the serum calcium is normal or slightly less than normal and the phosphorus raised. Differential diagnosis may be very difficult if there is inadequate evidence of the sequence of events.

Gout and arthritis may be simulated, especially if there are tender deposits of calcium in the joints, and some patients are treated for vague rheumatic pains or lumbago. In Paget's osteitis deformans, a disease of middle or old age, there is great deformity of the skull, normal calcium and phosphorus metabolism, but an increased serum phosphatase. Osteomalacia, or adult rickets is very rare in England and America, and is due to deficient intake of vitamin D or lack of sunshine. The bones are soft and deformed,

the plasma phosphatase is raised, and the plasma phosphorus is low, but the serum calcium is never above normal and is often below.

Albright has described a syndrome of multiple bone cysts and areas of rarefaction, segmentally distributed in relation to nerve roots, with corresponding patches of pigmentation. The disorder is found mostly in girls and in them is associated with sexual precocity, a feature not present in the male. The disorder may be mild and overlooked in childhood, and when presenting itself in the third decade may be mistaken for hyperparathyroidism. Apart, however, from the clinical differences, there are no changes in calcium, phosphorus, or phosphatase values. The ætiology is uncertain, and parathyroidectomy useless.

Prognosis.—In the absence of surgery, the course of the disease is progressive deterioration, and death occurs within a few years. Weakness, wasting and deformities compel the patient to take to bed. Intercurrent respiratory infection may terminate life, while others die from uræmia or pyelonephritis.

Treatment.—Primary hyperparathyroidism can only be adequately controlled by removal of a parathyroid adenoma or, in the case of hyperplasia, of two or more parathyroid glands. Deep radiation is usually ineffective, and a high calcium and phosphorus diet is only mildly beneficial and not without danger in the presence of renal insufficiency. If at operation no adenoma is discovered, the exploration should be continued above and below the thyroid region, behind the œsophagus and into the upper mediastinum, for a parathyroid tumour is sometimes found in such aberrant positions. Even if an adenoma is found in the usual situation, the posterior aspects of the thyroid gland should be explored to see if a second adenoma is present, as may be the case. Where there is diffuse hyperplasia of all four glands, no less than three should be removed, and some surgeons remove a portion of the fourth as in sub-total thyroidectomy. Tetany may follow operation for adenoma or hyperplasia, and may appear within a few days of operation, or after a latent period of some weeks. If controlled medically (see under Tetany), it will tend to disappear after some weeks or months, when the remaining parathyroid tissue has undergone compensatory hyperplasia. It is obviously illogical to give parathormone, which would further decalcify the already softened bones. Following parathyroidectomy, the general symptoms, *e.g.* pains, weakness, anorexia, improve almost at once, but the bones may take several months to become normally calcified. The serum calcium immediately falls to normal or below normal, but the phosphatase tends to remain high for some months, being an indication of osteoblastic activity. The sudden change from high to low serum calcium may cause transitory visual and mental disturbances with some degree of apprehension.

HYPOPARATHYROIDISM

Synonym.—Parathyroid Tetany.

Definition.—A disease characterised by an irritability of the neuromuscular system due to a subnormal concentration of serum calcium, the latter being the result of deficient secretion of parathormone. All forms of tetany are due to subnormal concentrations of calcium, or of ionised calcium, in the serum, but this is not necessarily the result of parathyroid hypofunction.

Ætiology.—Idiopathic hypoparathyroidism occurs sporadically, and may do so at any age, but this form is comparatively rare, or perhaps not sufficiently well recognised. A familial incidence of hypoparathyroidism has been recorded, including examples of onset in infancy. The majority of cases follow thyroidectomy, and although this may be due to simultaneous removal of parathyroid tissue, a series of sections indicate that it is more frequently due to interference with blood supply. Other cases follow removal of a parathyroid tumour and the remaining glands appear to be temporarily hypoplastic; or when two or more hyperplastic parathyroid glands are removed in osteitis fibrosa diffusa. Parathyroidectomised animals show decreased urinary phosphorus excretion and rise in plasma phosphorus before changes in calcium metabolism are apparent. Later, however, there is a fall in serum calcium in spite of a positive calcium balance, and the animal dies in tetanic convulsions. Parathormone injections will prevent or correct the initial changes in phosphorus metabolism and the later calcium ones. Tetany also occurs in conditions other than hypoparathyroidism if the concentration of calcium in the blood falls below normal. Thus in rickets, osteomalacia and steatorrhœa there is a deficient absorption and utilisation of calcium. The increased demands for calcium in pregnancy and lactation may render a latent tetany manifest. Tetany may be found in alkalosis, the total serum calcium being normal, but the ionised fraction below normal; alkalosis may result from excessive vomiting, hysterical hyperpnœa, or alkaline medication.

Pathology.—In idiopathic hypoparathyroidism, the parathyroid glands may be atrophic, or replaced by fibrous tissue, fatty tissue, and a round-celled infiltration; in post-parathyroidectomy tetany, too much parathyroid tissue has been removed, or the residual parathyroid tissue has not yet had time to undergo compensatory hypertrophy.

Symptoms.—Following thyroidectomy and parathyroidectomy, symptoms may appear within the first 48 hours or may be delayed weeks or months. There is often a general irritability, nervousness and apprehension in addition to weakness. Paræsthesias, and muscular cramps and stiffness are common in the hands, especially on the ulnar aspect, but may also occur in the feet. These symptoms may be followed by, or from the first be associated with, muscular contractions of the hands and feet, giving the classical picture of carpo-pedal spasm. The so-called obstetric hand is produced by flexion at the metacarpo-phalangeal joints, extension at the interphalangeal joints, and adduction of the thumb. Spasm of the laryngeal muscles may produce hoarseness and stridor, and, if the bronchial muscles are also involved, respiratory distress and cyanosis result, sometimes with fatal convulsions or coma. A form of chronic pseudo-asthma associated with bronchial spasm is also a manifestation of hypoparathyroidism. Tetanic muscular spasms are not infrequently painful and may cause the patient to cry out in distress.

In chronic cases, ectodermal defects become apparent, e.g. brittleness and ridging of the nails, loss of hair, transverse ridging of the decalcified teeth. Blurring of vision, perhaps leading to blindness, is due to opacity of the lens (cataract), and minor degrees of the latter may be detected by slit lamp technique even in the absence of ocular symptoms. Muscular spasm may involve ocular muscles.

Various cerebral and mental disturbances may be associated with an

undetected chronic hypoparathyroidism. Thus changes in character, mental instability, anxiety, depression, impaired memory and intellectual capacity, and more rarely hallucinations, confusion, manic-depressive states, paranoia, and dementia, are met with. Major epilepsy and even petit mal are also rare manifestations. Migraine may be a presenting feature. There may be calcium deposits in the basal ganglia of the brain, demonstrable in radiograms.

Gastric spasm may produce pain and vomiting, and spasm of the bile passage simulate cholelithiasis, especially if associated with transitory jaundice. Laparotomy has been performed for symptoms suggesting appendicitis or perforated peptic ulcer; and ileal spasm may produce fatal ileus. Cardiac pain, a sense of constriction, and palpitations are met with, and the electro-cardiogram shows a characteristic prolongation of the Q-T interval.

Diagnosis.—Although in most cases diagnosis is obvious, mild degrees of hypoparathyroidism with general irritability, weakness and paræsthesias and only slight ectodermal deficiencies, may be unsuspected. The following classical signs may be of diagnostic value. Chvostek's is the production of contraction of facial muscles by tapping the facial nerve below the zygoma; Trousseau's is the production of carpal spasm by a sphygmomanometer band on the arm at a pressure just above systolic; Erb's is an exaggerated muscular contraction in response to minimal electrical stimuli. The failure to elicit one or more of these signs does not exclude the diagnosis. Biochemical evidence is often conclusive. In hypoparathyroidism the serum calcium is always below the normal value of 10 mg. per 100 c.c. (e.g. 6 mg.) and the plasma phosphorus is above the normal 3.5 mg. (e.g. 7 mg.); there is decreased urinary excretion of phosphorus and calcium. In a doubtful case, an experimental high phosphorus diet will depress the serum calcium and produce neuro-muscular symptoms, but this does not occur with normal parathyroids. It is interesting to note, however, that in cattle there is a form of tetany, which is the result of excessive phosphorus in the diet.

Treatment.—The logical treatment of hypoparathyroidism is solution of parathyroid, U.S.P. (parathormone), which acts by primarily increasing the excretion of urinary phosphorus and secondarily mobilising calcium from the bones and raising serum calcium. This form of treatment, however, has several disadvantages. Thus, it is useless in acute tetany because subcutaneous or intramuscular injections may take 8 or more hours to be effective and are variable in time and degree of effect. While intravenous injection is quicker it takes a few hours to act and, moreover, by this route there is a danger of a protein shock like reaction in some patients. Four hourly injections of 1 c.c. solution of parathyroid (20 units) intramuscularly or subcutaneously may, however, be effective after the initial latent period. Rarely, overdosage of injected parathyroid hormone results in nausea, vomiting, diarrhoea, failing circulation, dehydration, increased viscosity of blood, coma and death. With controlled serum calcium estimations, however, overdosage is a rarity and it is more probable that 40 units daily may not be adequate to control the disorder. Even when solution of parathyroid is effective at first, a refractory state sets in after some weeks. The latter is probably not due to the production of anti-hormonic substances in the blood, as in the case of other hormones, but to local tissue immunity since an intravenous injection of solution of parathyroid may be still effective.

Nevertheless, this refractory state renders prolonged therapy with solution of parathyroid an impracticable scheme.

The immediate treatment of acute tetany is the intravenous or intramuscular injection of calcium gluconate, 20 c.c. of a 10 per cent. solution, the effect being rapid and dramatic, but only lasting some hours. The injections must be administered slowly, but a little leakage from a vein has not the local deleterious effects of calcium chloride. It is obviously necessary to follow this emergency injection by large doses of calcium gluconate or lactate by mouth, e.g. 12 gms. daily in divided dosage. Calcium chloride is less pleasant to take, and in practice the theoretical value of the resulting acidosis is not appreciable. This is perhaps less true of the addition of 3 gms. of ammonium chloride, daily, in 1 gm. capsules. In many cases calcium gluconate or lactate by mouth is sufficient to control the tetany. If not, there should also be given vitamin D, which acts by increasing calcium absorption from the intestine and secondarily by increasing phosphorus excretion in the urine. The dosage of vitamin D, or calciferol, should be high; 50,000 to 200,000 units daily may be required. In severe cases these measures may still be ineffective, and then a derivative of irradiated ergosterol, called dihydrotachysterol, or A.T. 10, is of great value. It is not antirachitic, probably because it also causes considerable excretion of phosphorus from the urine, but it produces a great increase in calcium absorption from the intestine and a rise of serum calcium to normal or above normal. Like vitamin D it is of no use in emergency, the effect not being produced for some 24 to 48 hours. It is, however, cumulative in action, and the dosage should be controlled by periodic serum calcium estimations if hyperealcæmia (nausea, vomiting, calcium deposition in kidneys, albuminuria, etc.) is to be avoided. The urinary test of Sulkowitch is a useful indication of dosage, apart from serum calcium. The reagent consists of oxalic acid and ammonium oxalate in glacial acetic acid, and equal amounts of urine and reagent are mixed. If no precipitate occurs, the serum calcium is probably below 7.5 mg. per 100 c.c., as the renal threshold for calcium varies between 7.5 and 9; if there is a fine white cloud, the serum calcium values are probably normal, about 10; if the precipitate looks like milk, the values are pathologically high. Using this technique Albright gives 3 c.c. of dihydrotachysterol a day by mouth until calcium appears in the urine, after which 1 c.c., 3 to 5 times a week is usually adequate. Dihydrotachysterol is prepared in an oily solvent containing 5 mg. of the drug per c.c., and is administered by the oral route.

Diet in hypoparathyroidism is a matter of some controversy. High calcium diets (milk, cheese, egg yolk) have the serious disadvantage of also being high phosphorus diets. It is better, therefore, to have a normal diet, or preferably a low phosphorus diet, and supply the extra calcium as calcium lactate or gluconate. The keynote of a low phosphorus diet is to eat less of milk, cheese, egg-yolk, meat and nuts, and more of fruit, vegetables, carbohydrates, fats, and white of egg.

S. L. SIMPSON.

DISEASES OF THE SUPRARENAL GLANDS

The suprarenal glands consist of two parts, cortex and medulla, which are separate organs in the lower species. The cortex is of mesoblastic origin, while the medulla is ectodermal. The cortex is composed of lipid containing epithelial cells, arranged from without inwards in three zones, zona glomerulosa, z. fasciculata and z. reticularis. The inner portion of the latter is characterised by brightly staining granules (pigment zone). The medullary cells have an affinity for chromic acid stains, and are termed chromaffin cells. The adrenal glands are supplied by sympathetic nerves from the splanchnic and coeliac ganglia, but they are cholinergic.

The medulla secretes adrenaline (orthodioxyphephenylethanomethylamine), and although this substance is sympathomimetic and, on injection, can produce vasoconstriction, an increase of blood pressure, cardiac rate, blood sugar, and of the basal metabolic rate, and dilatation of the coronary arteries, and of the bronchial tubes, etc., the medulla is not essential to life, and in animals may be destroyed by cautery without obvious changes resulting. Further, it is even doubtful if there is a continuous secretion of adrenaline in normal circumstances, although it is certain that it is secreted under abnormal circumstances, e.g. exposure to severe cold, during fright or emotion, during infections, and in hypoglycemia.

The adrenal cortex is essential to life, and bilateral adrenalectomy results in death within 7 to 10 days. The following hormones have been isolated from the cortex: androsterone (androgenic), oestrone, progesterone, corticosterone, and desoxycorticosterone. The last appears to be an essential life-saving hormone, and has been synthesised from cholesterol. Corticosterone has only a fraction of the activity of desoxycorticosterone but this also is life-maintaining. The other hormones have no such action. Their sex influence is manifested under certain pathological, or experimental, conditions, although whether so under normal conditions is less certain. It is thought that the androgenic hormone is secreted by special cells which constitute a broad inner zone at birth, but soon after undergo involution, although they may become hyperplastic in virilism and pseudo-hermaphroditism. This zone has been termed the androgenic zone, and stains deeply with the Ponceau-fuchsin dye.

The chief function of desoxycorticosterone is the regulation of sodium metabolism, with an associated influence on water balance, chloride and potassium metabolism. After bilateral adrenalectomy, there is an increased excretion of salt and water, with a retention of potassium, and a corresponding fall in the serum values for sodium and chlorine, and a rise in serum potassium. (The normal values are sodium 320, chloride (as NaCl) 565, potassium 20 mg. per 100 c.c.) There is also a shift of fluid from the plasma to the viscera, especially the liver, and the muscles. The blood becomes viscous, and the plasma volume is seriously decreased. Desoxycorticosterone injections will produce a return to normal. The action of desoxycorticosterone on carbohydrate metabolism is, however, feeble compared with that of cortical extract. The latter will completely correct the depletion of hepatic glycogen and the fall of blood sugar that occur in the adrenalectomised

animal. Corticosterone is even more potent than cortical extract in its influence on carbohydrate metabolism.

ADDISON'S DISEASE

Synonym.—Hypocorticalism.

Definition.—A disease due to destruction and hypofunction of the adrenal cortex, and manifested by pigmentation, weakness, myasthenia, anorexia, loss of weight and hypotension. It was first described by Thomas Addison in 1849.

Ætiology.—The disease is found among all races, and in all climates. Males and females are affected about equally. It is commonest between the ages of 20 and 40, and rare in childhood and old age. Tuberculosis is the most frequent cause, but any infection or toxicosis may be ætiological.

Pathology.—In the case of tuberculous lesions, both the medulla and cortex are usually destroyed, except for small islets of surviving tissue. The gland is replaced by fibro-caseous tuberculous tissue, with areas of fibrosis, giant cells and lymphocytes. There may be associated tuberculosis elsewhere, rarely pulmonary. A history of gland or bone tuberculosis in childhood or in other members of the family is not uncommon. The next most frequent cause is atrophy of the cortex, of unknown origin, the medulla being scarcely affected. The cortex is almost entirely replaced by connective tissue and dilated capillaries, with infiltration of lymphocytes, plasma cells and leucocytes. The picture is more like a toxic necrosis than a simple atrophy. Rare causes are syphilis, amyloid disease, hæmorrhage, infarction, and malignant growth. The last may apparently produce the disease even when it involves the sympathetic nerve supply only, and not the actual glands.

Symptoms.—Weakness, loss of appetite, loss of strength, and pigmentation are the usual presenting features.

The onset is often gradual. Occasionally the patient may not be seen by a physician before a grave crisis has developed. This is especially so when pigmentation is not a conspicuous feature, in which connection, it is to be noted that pigmentation may be even absent in fair-skinned people and in acute cases. Usually the patient complains of feeling not well in a vague sort of way. He (or she) may be languid, lacking in strength, and easily tired. Appetite is poor, and there may be a special aversion to fatty foods. In more severe insufficiency, nausea and even vomiting are distressing features, while abdominal pain, rarely sufficiently severe to simulate an acute abdomen, is occasionally present. Pain and tenderness may be limited to the loin region above and internal to the kidney, or pain may be referred to the scapula or shoulder region as the result of irritation of the diaphragm by the diseased suprarenal. The absence of any pain is quite compatible with the disease, and in fact is even more usual. Constipation is common, but there may be intermittent attacks of diarrhoea, either spontaneous or following purgatives, and these may precipitate a crisis. Hiccups and yawning are symptoms which may be very intractable, and which indicate incipient deterioration. There is progressive loss of weight, myasthenia and general weakness.

Generalised pigmentation, usually involving the mucous membranes as well as the skin, is a classical sign of the disease. The pigment deposited on the mucous membranes and skin is the normal pigment, melanin. Cutaneously, it is deposited in the basal layer of the epidermis, but in amounts greater than normal. Brown patches and streaks may be found on the inner aspects of the cheeks, the soft palate and posterior portion of the hard palate, the sides of the tongue, the gums, and the mucous surface of the lips, especially at the corners of the mouth. The distribution of skin pigmentation is partly determined by exposure to light and irritation. Thus, it is most marked on the face and neck, dorsum of the hands and forearms, waist-line, garter area, axillary folds and vulva, and in areas of skin overlying bony prominences, e.g. knuckles, ischial tuberosities and ankles. The palms show no evidence of increased pigmentation, except in the interphalangeal creases. Occasionally there are scattered cutaneous pigmented spots on the face and body. The nails of the hands and of the feet may be pigmented and striated. A leucodermic pattern of pigmentation is rare but authentic. Although pigmentation is a classical sign of Addison's disease, it may be inconspicuous or even absent in fair-skinned people, or when the onset is acute.

There is considerable variation as to interference with sex function. In some there is none, while in others there is amenorrhœa or impotence. Hypogonadism is certainly not an essential feature. Many patients feel the cold badly, especially in more severe insufficiency. The body temperature may be normal or subnormal, with perhaps intermittent pyrexia, and the basal metabolism is rarely appreciably lowered, except in crisis. The systolic blood pressure is characteristically below 100 mm. of mercury, but this does not necessarily give rise to symptoms, and a normal blood pressure may persist for some time. Although in some patients the fasting blood sugar and carbohydrate tolerance curves may be normal, in others there is a chronically low blood sugar and clinical attacks of hypoglycæmia may even be fatal if unrelieved by glucose or adrenalin. There is an increased sensitivity to infections, shock, surgical trauma, hæmorrhage and drugs. Conjunctivitis is a minor manifestation, usually denoting inadequate therapy.

In crisis, the patient is collapsed, cold and restless. The latter feature may be intermittent, and stupor may be more characteristic. There is considerable irritability and intractability. The patient tends to curl up deep in the bed beneath the covering, and to resent interference. The pulse is rapid and of poor volume, and the blood pressure tends to fall acutely. Nausea, vomiting and diarrhœa may be persistent, thus adding to the dehydration that has resulted from the increased loss of salt and water through the kidneys. The veins are collapsed and the blood viscous on account of anhydramia. Ultimately urine becomes scanty in amount, and terminally may contain casts and albumen. Pigmentation tends to increase in the more severe degrees of insufficiency, and crops of discrete deeply pigmented spots may appear. Blood sugar concentration tends to fall to hypoglycæmic levels in a crisis, the serum sodium and chlorine levels become even lower than previously, and the serum potassium concentration higher. In man it would appear that the changes in mineral metabolism are even more important than those in carbohydrate metabolism, and in adrenalectomised mammals death occurs, even when a normal blood sugar concentration is maintained by intravenous glucose infusions.

Complications.—Addison's disease may be complicated by thyrotoxicosis or by diabetes but these are rarities. Other tuberculous lesions or intermittent infections, such as pneumonia, are not uncommon.

Diagnosis.—Clinically, this depends upon the classical features of pigmentation, weakness, wasting, anorexia and hypotension. Cutaneous pigmentation may also occur in other conditions, including hæmoehromatosis, Hodgkin's disease, exophthalmic goitre, pernicious anæmia, arsenical poisoning, malignant cachexia, ochronosis, argyria, parasitic irritation, leucoderma and pregnancy. In Simmonds's cachexia, a condition which has many features in common with Addison's disease, pigmentation is usually absent and is hardly ever diffuse, or marked. It is important to note that pigmentation of the mucous membranes is practically pathognomonic of Addison's disease. It is said by some to occur very rarely with pernicious anæmia, malignant cachexia and arsenical poisoning. Of the first, I wish to record that two authorities on pernicious anæmia have never met with pigmentation of the mucous membranes in this disease. In people of the negro race, or in those with an antecedent negroid admixture, pigmentation of the mucous membranes may occur normally.

If the serum sodium and chloride (expressed as Na Cl) are in low concentration (*e.g.* 295 and 530 compared with normal 320 and 565 mg. per 100 c.c. respectively), the diagnosis of Addison's disease is confirmed. Normal values at any one time, on the other hand, do not contraindicate the diagnosis. The serum potassium may be normal in moderate insufficiency, 18–20 mg., but in severe phases may be as high as 36 mg. per 100 c.c. A raised blood urea or low blood sugar is supporting evidence, but both of these may be normal. The Cutler diagnostic test of measuring renal excretion of sodium chloride on a diet low in salt and with potassium added, has been discarded, because of the danger of precipitating a crisis. As a safe modification, the Kepler test is now used, and I find it of considerable diagnostic value. In my experience, however, a positive result is obtained in both Addison's disease and Simmonds's disease (which see), as the test measures adrenal cortical function, which is also seriously impaired in the latter disorder.

Kepler test.—*Procedure 1.*—On the day before the test the patient eats three ordinary meals but omits extra salt. He is requested not to eat or drink anything after 6 o'clock in the evening. Until this time he may drink water as desired. At 10.30 p.m. he is requested to empty his bladder and discard the urine. All urine which is voided from then on until and including 7.30 a.m. is collected. The volume of this urine is measured and saved for chemical analysis if this should be necessary later. Breakfast is omitted. The patient is asked to void again at 8.30 a.m., and immediately thereafter he is given 20 c.c. of water per kilogram of body weight (9 c.c. per pound). He is asked to drink this within the next forty-five minutes. At 9.30, 10.30, 11.30 a.m. and 12.30 p.m., he is requested to empty his bladder. In order to eliminate the effects of exercise and posture on urinary excretion, he is kept at rest in bed except when up to void. Each specimen is kept in a separate container. The volume of the largest one of these four specimens is measured.

Under these conditions some patients having Addison's disease will excrete so little urine that they are unable to void more than once or twice during the entire morning. In such instances the amount of urine excreted per hour may be calculated; frequently, however, such calculations are unnecessary because of the very low urinary output throughout the entire morning.

Inferences that may be drawn from Procedure 1.—(1) If the volume of any single hourly specimen voided during the morning is greater than the volume of urine voided during the night, the response to the test is negative, that is, such a response indicates the

absence of Addison's disease. (2) If the volume of the largest hourly specimen voided during the morning is less than the volume of urine voided during the night, the response to the test is positive, that is, Addison's disease may or may not be present. To establish the diagnosis Procedure 2 should be instituted.

Procedure 2.—Blood is drawn while the patient is still fasting, and the plasma analysed for its content of urea and chloride. The specimen of urine which was voided during the night is also analysed for urea and chloride. From these four determinations and from the results obtained from Procedure 1 the following equation is solved :

$$A = \frac{\text{Urea in urine (mg. per cent.)}}{\text{Urea in plasma (mg. per cent.)}} \times \frac{\text{Chloride in plasma (mg. per cent.)}}{\text{Chloride in urine (mg. per cent.)}} \\ \times \frac{\text{Volume of day urine (c.c.)}}{\text{Volume of night urine (c.c.)}}$$

The term "day urine" applies to the largest of the hourly specimens voided during the day; "night urine" to the entire amount which was voided from 10.30 p.m. to 7.30 a.m. If the value of A in this equation is greater than 30, the patient probably does not have Addison's disease. If the value for this equation is less than 25, the patient probably has Addison's disease provided that nephritis has been excluded.

When tuberculous lesions of the adrenal glands have become calcified, radiology may be of diagnostic help by revealing calcareous shadows in the costo-vertebral angle.

Prognosis.—In the absence of treatment, there is progressive deterioration and death within months or years. With adequate substitution therapy, life may be prolonged, but the sensitivity to intercurrent infection is always a danger. Occasionally there is a spontaneous recovery of adrenal function sufficient to permit the cessation of substitution therapy.

Treatment.—As in other hormone deficiencies, the essential treatment is substitution. Cortical extract (obtained from the suprarenal cortex) is given by intramuscular, or intravenous, injection, and the daily dosage varies between 5 and 20 c.cm. The most severe cases, however, require 30 c.c. or even 40 c.c. daily, and in these circumstances cost and mechanical difficulties render the maintenance of life precarious and painful. Cortical extract is standardised on adrenalectomised dogs or rats. A considerable advance was made by Loeb's discovery of the value of salt therapy. The dosage of sodium chloride is 3 teaspoonfuls, or some 12 grams, daily, taken with water, milk, bovril, lime-juice, porridge and salads. In some patients the salt treatment produces nausea and vomiting as in the case of normal people, so that it must be discontinued, but others can tolerate it quite well. Mild cases need no other special treatment, but in the more severe cases cortical extract must be administered as well, though the salt permits a reduction in the dosage of cortical extract.

A distinct advance in therapy was made when Reichstein isolated from the adrenal cortex and also synthesised from cholesterol a substance called desoxycorticosterone (or desoxycortone) which appears to be an essential hormone of the adrenal cortex. It is prepared in ampoules of 5 mg. in 1 c.c. sesame or arachis oil, and is injected intramuscularly. It would appear that 5 mg. of desoxycorticosterone is equivalent to 10 or more c.c. of cortical extract, and the acetate of desoxycorticosterone is normally employed for a more gradual action. Usually the injections are painless but a few patients react with red hot lumps at the site of injections, and the local reactions, apart from being painful, appear to interfere with absorption of the hormone. Persistence with therapy, however, may in some patients be followed by

disappearance of the local reactions. There is an alternative, and in some respects preferable, method of using desoxycortone acetate. Thus sterile tablets, 100 mg. each, may be inserted under local anaesthesia, in the subcutaneous fat of the abdomen, or intrascapular region, either by open minor operation or by using a trocar and cannula. The dosage is calculated from the daily requirements of preliminary injections of desoxycortone, and in my experience a 100 mg. tablet is equivalent to 0.8 mg. injected daily. Thus 6 tablets would be used for a person requiring 5 mg. of desoxycortone daily, and it is prudent not to use more than 600 mg. for an initial implantation, although more severe insufficiency will require an increased dosage. The tablets are gradually absorbed over a period of 6 to 10 months. It is best to make the initial calculation without counting upon supplementary salt, and after six months, as the tablet effect wears off, supplementary salt by mouth may be added. Desoxycortone is also effective by cutaneous inunction when dissolved in benzyl alcohol (20 mg. in 1 c.c. being equivalent to 5 mg. by injection), but this preparation is not generally available, and it is a very expensive method of therapy. Another method of use is by sublingual absorption of tablets or solution, but in my experience this is an uncertain and not consistently effective method for this hormone.

As to the choice between cortical extract and synthetic desoxycortone, the former has all the theoretical advantages, containing both the carbohydrate regulating and salt-water retention hormones, while desoxycortone has only the latter effect. Nevertheless, desoxycortone is easier to administer and appears to be very effective in many patients. During infections, however, or in severe insufficiency, cortical extract should always be used as a supplementary therapy. Corticosterone, the carbohydrate regulating hormone, has been synthesised and should be available commercially later on, but the crude chemical extract of the suprarenal gland probably contains less well defined additional hormones, and an amorphous fraction has been shown to do so.

Desoxycortone has a very powerful specific effect on retention of sodium chloride and water, and on the excretion of potassium, and its use must be attended with every caution, as overdosage may result in disaster. Thus oedema of the face, arms and legs, and of the lungs, heart, and viscera, pleural, pericardial, and peritoneal effusions, hypertension and widening of the heart shadow (cardiac-pulmonary radiographic ratio) have all been observed and recorded. The hypertension and superficial oedema have, however, been unduly stressed, and it is not generally recognised that the other internal effects, *e.g.* oedema of the lungs, may occur in the absence of hypertension or superficial oedema. This is also true of a severe muscular weakness, comparable to that of periodic familial paralysis, and due to the low potassium concentration, *e.g.* 12 mg. per 100 c.cm. This increased excretion of potassium is probably a specific effect, as it may occur in association with normal serum values for sodium and chloride, and this observation, too, has not been recorded or recognised. In doubtful cases, therefore, it is important to have serum potassium estimations carried out as a guide to therapy. The response to desoxycortone varies with different individuals, and I have met with one patient who produced a superficial oedema after two daily injections of 2 mg. The dangers of overdosage with desoxycortone are increased by the giving of additional salt by mouth, and this should only be done, if at all, cautiously.

and with biochemical controls. Nevertheless, the high cost of desoxycortone makes additional salt necessary in many cases. It is generally believed that it is impossible to give an overdose of the crude cortical extract, but this is not the case, as the extract also contains the desoxycortone factor, and if given in large enough doses, *e.g.* 40 c.cm. daily, salt-water retention and dangerous depression of serum potassium values can occur. It is my opinion that other hormones of the adrenal cortex must be isolated before a properly balanced therapy for the most severe cases of adrenal insufficiency will be possible, without the danger of overdosage from one element. A low potassium diet, advocated by some workers, is fortunately difficult to prepare, but from what has been written above, it will also be seen as dangerous therapy.

In crisis, treatment is obviously intensified. Five mg. of desoxycortone is given every 8 hours, alternating with 20 c.c.'s of cortical extract every 8 hours, so that some therapy is given 4-hourly. The initial doses may be doubled. In view of the dangers recorded above, I prefer not to give intravenous saline and glucose unless the dehydration is extreme, and even then the subcutaneous or rectal route may be preferable. As diabetic coma may insidiously pass over to insulin coma, so may an Addisonian crisis pass over imperceptibly to the crisis of overdosage unless the most careful clinical and biochemical observations are made. The effects of overdosage may be corrected by mersalyl suppositories and potassium citrate by mouth.

The treatment of the underlying tuberculosis, when the presence of such is established, is carried out on general lines, but the writer has not seen appreciable benefit resulting from tuberculin injections. Injections of the adrenotrophic hormone of the pituitary gland have been advocated, but here too the writer's experience has not been favourable. Nor have I seen appreciable benefit from supplementary therapy with progesterone, or testosterone, both of which have been recommended. A graft of the adrenal glands of an infant, born dead because of mechanical difficulties and from healthy parents, can be effectively grafted into the rectus abdominis. If the graft is successful, beneficial effect will result, but the glands are gradually absorbed and rarely does the benefit last more than 6 months. It is not a method of treatment which can rival modern chemical therapy.

ACUTE SUPRARENAL DEFICIENCY

Apart from Addison's disease, there is some clinical and pathological evidence that acute adrenal insufficiency occurs with certain infections, such as meningococcal septicæmia, diphtheria, typhoid fever, and pneumonia. At autopsy, the suprarenals may show congestion, œdema, hæmorrhage, and necrosis.

The onset is sudden. Malaise, restlessness, headache, vomiting, fever, chills, sweating, abdominal pain, cyanosis, scattered petechæ, and stupor or coma, are characteristic features of the malady. When the underlying lesion is acute bilateral suprarenal hæmorrhage, the term Waterhouse-Friderichsen syndrome has been applied to the clinical condition. This syndrome is usually associated with meningococcal septicæmia, and is more frequently met with in infants than in adults.

Acute suprarenal insufficiency may also complicate surgical shock and

severe burns, the biochemical changes in the blood resembling those found in the more severe phases of Addison's disease.

Diagnosis.—The diagnosis of acute suprarenal insufficiency as a complication of infections, surgical shock, and burns, is often a matter of assumption, based on experimental evidence. That of the Waterhouse-Friderichsen syndrome is only occasionally made in life, but is suggested by early cyanosis, collapse and fall of blood pressure in a patient suffering from a meningococcal infection.

Treatment.—Treatment is similar to that described for the crisis of Addison's disease.

ADRENO-GENITAL SYNDROME

Synonym.—Virilism.

Definition.—A combination of amenorrhœa (or oligomenorrhœa), adiposity and hirsutism, associated with neoplasm or hypertrophy of the adrenal cortex. Adiposity is not invariably present, but in its absence the name adreno-genital is still justified. Examples of hirsutism without amenorrhœa, or oligomenorrhœa, are met with, but cannot be classified as adreno-genital syndrome. Hirsutism indicates excessive hairiness on the face and body in the female, and of male type distribution. The theoretical distinction between adreno-genital syndrome, and the more complex Cushing's syndrome (which see) is not always possible in practice, and intermediate clinical types are met with.

Ætiology.—The immediate cause is hypersecretion of androgenic hormone by the adrenal cortex, which also inhibits the gonadotrophic function of the pituitary. There appears to be a greater incidence among Jewish and Mediterranean people. There is, however, no sharp dividing line between milder cases of the disorder and accepted normality.

Pathology.—The lesion is an adenoma, a carcinoma, or a bilateral hypertrophy of the adrenal cortex. The cells have an affinity for the ponceaufuchsin stain, and are thought to arise from the inner androgenic zone of the cortex. There may be a general lymphoid hyperplasia, and a large thymus. The ovaries tend to be atrophic.

Symptoms.—The changes usually begin at or soon after puberty, but may not become prominent until the late teens, or sometimes in the twenties, or later. The essential feature is an excessive growth of hair on the side of the face, the upper lip and chin, the forearms, thighs and legs and on the trunk. The last may be only slightly affected in the form of a linear growth of hair extending from the usual feminine horizontal upper limit of pubic hair upwards along the linea alba to the umbilicus; or the hair may cover the abdomen and chest, and tufts of hair surround the nipples. Menstruation may cease altogether, or may be only scanty and at long intervals. The uterus may become small or may fail to develop, but more usually there is no gross change in its size. The clitoris may be normal or appreciably enlarged, sometimes resembling a small penis. The breasts may be atrophic or undeveloped, but with adiposity this fact is obscured. An increase of weight due to adiposity, although not invariable, is frequently met with, fat being deposited on the face and neck, breasts, abdomen and pubis, and

upper parts of the arms and thighs; the legs and forearms may be quite thin and graceful. There is a group of cases characterised by an absence of adiposity, but with considerable muscular development and strength, and broad shoulders and narrow hips, as in the masculine build.

Complications.—Some degree of pigmentation around the eyes may be met with. Weakness and changes in mineral metabolism similar to those in Addison's disease have also been noted, presumably due to the encroachment of the androgenic cells on the other secreting cells of the adrenal cortex. Psycho-neurosis and psychosis, with loss of heterosexual desire and homosexual tendencies, may be complications. A complete feminine mentality, however, may be associated with virilism, and the fear of sex conversion and of feminine inadequacy is poignant.

Diagnosis.—A combination of hirsutism and amenorrhoea makes diagnosis obvious. A tumour should be suspected if the disease has started after the twenties in a person hitherto quite normal, and in no case can be excluded without investigation. Considerable enlargement of the clitoris is more common with a tumour, but may be present with hyperplasia. Intravenous injection of uroselectan combined with radiography may demonstrate a neoplasm. A more certain method, though not without danger, is perirenal insufflation of 450 c.c. of air, the neoplasm being shown surrounded by air in the skiagram. Ovarian tumours (arrhenoblastoma) may produce virilism; they are not always palpable on vaginal examination, and may be revealed by laparotomy.

Androgenic hormone is usually secreted in excess in virilism. If the quantity of 17-ketosteroids excreted in 24 hours is greater than 20 mg. (normal 5 to 12 mg.) an adrenal tumour should be suspected, although higher values than this may be found with simple hypertrophy. Occasionally enormously high values, 180 mg., may be found with an adrenal tumour. If, after removal of an adrenal tumour, the values for 17-ketosteroids fall and then rise again to high levels, malignant metastases or a tumour of the opposite adrenal gland should be suspected. This sometimes occurs. Hypertrophy of the adrenal cortex, and more rarely neoplasm, can occur as a complication of acromegaly, presumably as a result of excessive adrenotropic hormone.

Prognosis.—In the case of hyperplasia the condition may be stationary or only slightly progressive for many years. Sterility is the rule, but one child may be born. The successful removal of an innocent tumour may produce a reversion to normal. Carcinoma of the adrenal cortex is very malignant, and metastases or recurrences are the rule.

Treatment.—A tumour should be removed surgically. It is important to give cortical extract for a few days before and after the operation, since the opposite adrenal may be atrophic and the patient may die from acute adrenal insufficiency before this adrenal has had time to undergo hypertrophy. For bilateral hyperplasia, unilateral adrenalectomy is advocated, but although the operation may be followed by return of menstruation and temporary weakening of the hair growth, it is rare for the hirsutism or the adiposity to be permanently influenced. It would be more logical theoretically to remove one whole gland and three-quarters of the other as in subtotal thyroidectomy, but the obvious danger is the production of adrenal insufficiency, and Addison's disease has been recorded following such radical

surgery. Large doses of œstrin by injection or by local inunction have been indicated, but here too the writer's experience is disappointing. X-ray treatment of the hirsutism has various disadvantages (burns, scars). This is less true of electrolysis, which may be helpful.

There are many instances of hirsutism without any disturbance of menstruation. In such cases, also, it is very important to try and give some philosophical or psychological comfort, though not an easy task. Since in actual fact we are here dealing with a variety of normality, it is to be wondered to what degree intersexuality will ultimately be commonly accepted by the non-medical world. It is, after all, a reality.

FEMINISATION

This condition is a rarity compared with virilism. It is due to a tumour of the adrenal cortex in the male, usually malignant. There is a loss of libido and sexual potency, with a general increase in fat deposition and a hyperplasia of the glandular tissue of the breasts. The latter become enlarged, the nipples pigmented and the superficial veins dilated. There may even be some secretion, which can be expressed from the nipples as in incipient lactation. The patient usually dies from malignant metastases, but in one case successful removal of the tumour led to a return to normality. The testes on section show atrophy. It is interesting to note, and of diagnostic significance, that whereas adrenal cortical tumours producing virilism in women secrete very large quantities of androgens, similar tumours (not capable of histological differentiation) producing feminisation in man, secrete enormous quantities of œstrogens, *e.g.* 4000 mouse units in 24 hours. There is a return to normal values, *e.g.* 200 mouse units, on removal of the tumour, and increasing values if malignant recurrence or metastases follow.

PSEUDO-HERMAPHRODITISM

Definition.—Pseudo-hermaphroditism is a condition in which there is only one type of gonad, testis or ovary, but in which the external genitals are a mixed representation of male and female characteristics, or characteristic of the opposite sex to the gonads. Strictly the term should be applied only to those cases in which the condition is present from birth, and not to those instances of virilism or feminisation which appear in later life. It is also not intended to include under this heading sexual precocity in the female due to an adrenal tumour and associated with hirsutism. Classification according to the type of gonad is the simplest, *i.e.* testicular pseudo-hermaphroditism and ovarian pseudo-hermaphroditism.

Ætiology and Pathology.—Gross hyperplasia of the adrenal cortex occurs in only 14 per cent. of pseudo-hermaphrodites, but it may well be that hyperplasia of the sex cells (androgenic zone) could be detected in a far greater proportion by the ponceau-fuchsin stain. It is certainly possible to produce symptoms of pseudo-hermaphroditism in the experimental animal (rat, guinea-pig, fish) by injecting large doses of androgens or œstrogens into the young animal or into the pregnant mother. Nevertheless, it is probable

that the hyperfunction of the adrenal cortex is a mechanism, essential or concomitant, but primarily determined by genetic or chromosomal factors.

The seminiferous tubules are not completely developed, and spermatogenesis is usually absent, but the interstitial cells may be normal or hyperplastic. The ovaries are hypoplastic, fibrotic or cystic.

Symptoms.—(A) **TESTICULAR PSEUDO-HERMAPHRODITISM.**—The commonest and most easily understood type is the male in whom the formation of the external genitals is incomplete, the two scrotal folds remaining united (cf. hare lip), and enclosing a vagina-like cavity, one or more inches in depth. The penis may be incomplete, or hypospadias of varying degree may be present, or the penis may be so inadequately developed as to represent a clitoris. The patient is then brought up as a girl, until the appearance of masculine hair at puberty and the failure to menstruate lead to further investigation. The vagina is found to be false, the uterus absent, and the gonads testicles. The last, being retained in the abdomen, have the characteristics of cryptorchid testicles, namely, absence or destruction of the spermatic tubules, and increase in the interstitial cells. Nevertheless, the secretion of male hormone may be deficient, and the patient be of eunuchoid type. Chapple has described the case of a young, beautiful woman, with no hirsutism, with a female figure, well-developed breasts, and normal feminine libido, who in spite of a short vagina had satisfying intercourse with males. She came under observation for painful lumps in the groin, which were found to be testicles. No uterus could be detected. It is more usual, however, for the testicular pseudo-hermaphrodite to have hirsutism and other secondary male sexual characteristics. Although the testis secretes as much oestrone as the ovary (and the female about as much testicular hormone as the male), it is difficult to understand why, of two pseudo-hermaphrodites with testes and female external genitals, one should have male hair and bodily form, and another be a beautiful female. Obviously the genetic factors may be more important than the endocrine. As regards the sexual organs other than the gonads there is a considerable variation, with the following possibilities in the case of a testicular pseudo-hermaphrodite: hypospadias only; with a vagina; with a vagina and Fallopian tubes; with a vagina, uterus and tubes. The testes may be in the pelvis, the inguinal canals, the labia, or in the scrotum.

(B) **OVARIAN PSEUDO-HERMAPHRODITISM.**—The female pseudo-hermaphrodite possesses ovaries, but has a masculine configuration, with the external genitals simulating those of the male. The basis of the condition is difficult to explain unless it is assumed that it is comparable to the adrenal virilism of the adult, and due to hyperfunction of the adrenal cortex commencing in foetal life. Although to be within our definition such cases should show abnormalities at birth, these may not be gross until later childhood and may be further accentuated at puberty. The psychic and sexual behaviour of the pseudo-hermaphrodite varies in different individuals, and is often independent of the physical or endocrine basis. Thus the hirsute, testicular pseudo-hermaphrodite may be essentially feminine in outlook and libido, and capable of functioning to complete satisfaction of herself and partner in coitus. Some are ambisexual. Apart from indisputable pseudo-hermaphrodites, it is obvious that a number of people have the physical characteristics (apart from genitals), emotional reactions and libido of the opposite sex.

Diagnosis.—The recognition of the condition of pseudo-hermaphroditism is not difficult, although it may not become evident to the lay person until late childhood or puberty. The elucidation of the underlying pathology may, however, be impossible unless laparotomy is undertaken. Many patients present themselves with lumps in the inguinal canal, and it is only after removal and section of these gonads that the real sex can be determined.

Prognosis.—From the nature of the disorder it is unreasonable to expect a fundamental improvement, with or without treatment. The latter may ameliorate the condition.

Treatment.—If help is not sought before adult life, treatment should depend upon the sexual inclinations of the patient. If these are female, the clitoris should be amputated and, if necessary, the vagina enlarged. The removal of testes will diminish the hirsutism. In the child the removal of testes would prevent hirsutism, but in view of some testicular pseudo-hermaphrodites having beautiful feminine configuration without hirsutism and the fact that the testis does secrete oestrogens, it is considered by some better to wait until puberty gives an indication of what is likely to develop. When the outlook and libido are masculine, a plastic operation can repair or create a scrotum and abolish the hypospadias. With ovarian pseudo-hermaphroditism the question of unilateral adrenalectomy arises, or the more drastic procedure of two-thirds resection of both adrenal glands. Good results have been reported, but the value of the procedure is still *sub judice*. Laparotomy may reveal that an apparent instance of pseudo-hermaphroditism was in fact the rarer condition of true hermaphroditism. Experience suggests that it is unwise to speculate too much in the absence of laparotomy.

HERMAPHRODITISM

True hermaphrodites have both male and female gonads, namely, one testis and one ovary, or an ovo-testis in one organ. They are extremely rare, and it is probable that up to the present time not more than 20 cases have been described. Hermaphroditism is normal for some of the lower species, *e.g.* the worm, and is not a rarity among pigs and goats. In the hen, the right gonad is rudimentary, but if the left ovary is removed the right gonad becomes a testis and the hen grows a comb. Further, any remnant of the left ovary that is left behind may grow into testicular tissue, since the medulla of the ovary is the homologue of the testis. The change of sex in the hen may be so complete that the mother of chicks may become the father of chicks. In man the external genitals may give no indication of the internal genitals. Young, in 1933, described what he regarded as the twelfth case of true hermaphroditism on record. A young "male," tall and athletic, with penis and scrotum, and masculine hair, came to operation for undescended left "testicle." On opening the left inguinal canal, it was found to contain a uterus, Fallopian tube and functionary ovary. A portion of the right gonad in the scrotum was excised, and a section showed normal testicular tissue.

Although the adrenal cortex is frequently hyperplastic in true hermaphroditism, there is no evidence that this is the principal aetiological factor. On the contrary, the cause of true hermaphroditism would appear to be genetic,

and the inherent mechanism gonadal. The importance of the genetic factor is well illustrated by the bullfinch, which may have a testis on the right and an ovary on the left, with masculine plumage on the right half of the body and feminine plumage on the left half. Huggins, Cohen and Harden reported another type of true hermaphroditism in which the patient was brought up and behaved as a woman, and one gonad was a testis and the other an ovotestis, both removed from the inguinal canal and examined histologically. The patient was athletic and slightly hirsute. She had a normal vagina and uterus, and began to menstruate at the age of 14, at which time the clitoris became grossly enlarged and assumed the size of a small penis.

ADRENAL MEDULLARY TUMOURS

Tumours of the medulla of the suprarenal gland may be benign or malignant. Those arising from the chromaffin cell of the suprarenal medulla are termed phæochromocytomas or paragangliomas and contain large quantities of adrenaline. The latter is secreted into the blood paroxysmally, producing hypertensive crises. Thus, a previously healthy young adult may develop attacks of hypertension, palpitation, pallor, nausea, vomiting and cyanosis of the extremities; the systolic blood pressure may rise from 130 to 300 mm. of mercury, the change in the diastolic usually being much smaller. During the temporary rise of blood pressure, the patient complains of agonising headache, and a sense of constriction in the chest with, perhaps, angina-like pain. There may be transitory hyperglycaemia and glycosuria, and albuminuria. The pallor and coldness of the skin, especially of the extremities, may be associated with, or followed by, profuse perspiration. Shivering, cramps of the calf muscles, mydriasis and pyrexia are other features. These paroxysmal attacks may recur at increasingly frequent intervals, and the symptoms of hyperadrenalism may persist in lesser degree between the paroxysms. Hypertrophy and degeneration of the arterioles are found in the more chronic cases, and the kidneys may show ischaemic fibrosis. Removal of a medullary tumour will result in abolishing the symptoms, if the operation is done early enough. Occasionally, bilateral tumours are met with.

Neuroblastoma, or sympathoblastoma, are tumours arising from the embryonic sympathetic nerve cells in the medulla. They have no endocrine function. They are very malignant, and metastases to the orbit skull and long bones (Hutchison type) or the lungs and liver (Pepper type).

THE SEX GLANDS

Hypogonadism may be secondary to failure of pituitary function, as has been described in previous articles, *e.g.* Simmonds's disease and Fröhlich's syndrome; or it may be a primary failure of testicular function, *e.g.* eunuchoidism; climacteric. The latter condition in males is not generally recognised, but is met with in some men over 50, with loss of libido and potency, hot flushes, anxiety and inability to concentrate; the symptoms are ameliorated by testosterone therapy. Impotence in man is not infre-

quently met with at all ages, and is usually psychogenic. Whereas organic impotence, *e.g.* after traumatic castration, responds dramatically to testosterone, psychogenic impotence does not. The latter is ameliorated or cured by appropriate psychotherapy. Temporary functional impotence is more common than is generally realised, and is caused by excessive anxiety or fatigue.

EUNUCHOIDISM

Definition.—A condition of primary hypogonadism, or agonadism, occurring in either sex, and originating in embryo, or before puberty. The term of eunuchism is sometimes applied to complete absence of gonadal function.

Ætiology.—The condition is often genetically determined, and there is no obvious cause for the failure of gonadal development; or it may result from bilateral testicular atrophy following mumps, or, rarely, operation for bilateral inguinal hernia. Very rarely, also, both gonads may be involved in strangulated hernia, and be removed. In certain religious sects castration is performed before puberty in all males, and this operation was at one time carried out to provide eunuchs (meaning 'guardian of the couch') in harems.

Symptoms.—The epiphyses of the long bones remain open until the third or fourth decade, or longer, and as there is no deficiency of growth hormone, all true eunuchoids tend to be tall, often very tall. The length of the limbs is much greater than the measurement from the head to the pubis; in normals such measurements are approximately equal. The testes are absent, atrophic, or infantile, and the penis small and flaccid. Libido and potency in the male are absent. The uterus and vagina are infantile in the female. The secondary sexual characteristics are absent in both sexes, *e.g.* the male has a smooth hairless face and high-pitched voice, and the female absent breasts and narrow hips. The male pelvis may be of neutral type, or unusually broad for a man. Pubic hair may be present, but it is scanty and limited horizontally. There is a thin type and a fat type, which fact complicates our conception of the disease, but this appears to depend on an inherent endocrine constitution. Thus, whereas in cattle, sheep and oxen, castration is undertaken to produce fatness and invariably *does so*, in dogs early castration produces fatness in only some 50 per cent. Further, ovariectomy after puberty in women may produce no change in weight whatsoever, or moderate fatness, or enormous adiposity, *e.g.*, six stone gain in six months. Even the thin eunuchoids tend to put on weight after the age of forty.

Diagnosis.—Theoretically, and from clinical observations alone, it is not possible to differentiate between primary failure of gonadal development, or primary failure of the gonadotrophic function of the pituitary, providing it is granted that one single function of the pituitary can fail. Further, when adiposity is present, it is not always possible to differentiate the condition clinically, without treatment, from Fröhlich's syndrome, except that a eunuchoid is tall and a Fröhlich patient is of normal or subnormal height. However, in Fröhlich's syndrome, due to pituitary deficiency, the testes will respond to gonadotrophic hormone, whereas in eunuchoidism there is no response to gonadotrophic hormone.

Treatment.—This is essentially substitution therapy, and the results of testosterone therapy in the male are dramatic. Primary and secondary sexual characteristics develop, together with increased strength and well-being. Libido and potency approximate to normal, and coitus is satisfactory except that ejaculation is absent or slight. The testes, if present, remain infantile or atrophic, and the patients remain sterile. Testosterone can be given by injection, 50 mg. twice weekly, or by subcutaneous implantation, *e.g.*, six tablets of 100 mg. each, the effect of the latter lasting 8 to 12 months. Methyl testosterone, 5 mg. tablets, by mouth or under the tongue, three times a day, is also effective. In the female, oestradiol or hexoestrol produces breast and uterine development, and increased well-being.

CLIMACTERIC

Synonym.—Menopause.

Definition.—The climacteric, or “change of life,” occurs in women about the age of 45 to 50, and its manifestations are due to the cessation of ovarian function and associated changes in the pituitary and adrenal glands. Menopause refers more precisely to the cessation of menstruation. It is one feature of the climacteric.

Ætiology.—The primary disorder appears to be cessation of ovarian activity, the ovaries ceasing to respond to gonadotrophic stimuli. There is a secondary hyperactivity of the anterior pituitary gland, and possibly of the adrenal cortex. The pituitary secretes an excess of follicle stimulating hormone, but apparently ceases to secrete luteinising hormone. The ovaries become atrophic and fibrosed.

Symptoms.—A great deal depends on the endocrine constitution of the individual. Some women experience almost no symptoms or signs. Others may suffer severe disturbance. Vasomotor instability is manifested by hot flushes over the face and neck, alternating with cold sweats. There is an increase in fat and weight, sometimes very considerable. Hair may grow or increase on the lips and chin, a manifestation of increased activity of the adrenal cortex. Anxiety, nervousness, irritability, emotionalism, tremors and palpitations, may change personality and behaviour pattern. Hypertension may develop at this time, and may disappear spontaneously after months or years, or may be permanent. Pruritus is often troublesome. Many diseases, such as exophthalmic goitre, diabetes mellitus, rheumatoid arthritis, and migraine, may have their onset at this time of life, although not necessarily caused directly by the endocrine changes occurring at the climacteric.

The climacteric changes and symptoms often go on for a period of several years, and may even recur after an interval of several years' freedom from disturbance. That they are not entirely brought about by cessation of ovarian activity is indicated by the effects of bilateral ovariectomy in younger women, *e.g.*, 30. The operation may or may not be followed by climacteric symptoms, but in any case at the age of 45 to 50, although menstruation ceased 15 years previously, climacteric symptoms may make their appearance.

Prognosis.—Vasomotor, neurotic, and hypertensive symptoms tend to disappear spontaneously after some months or years, but adiposity and hirsutism, if present, may remain.

Treatment.—Oestradiol, stilboestrol or hexoestrol, is specific therapy,

and has a dramatic success in abolishing vasomotor symptoms and ameliorating neurotic symptoms. Œstradiol is the natural hormone, and its administration is free from any toxic effects. It is expensive, and both stilbœstrol and hexœstrol are as equally effective, but both may produce nausea and vomiting in some patients, and of the two hexœstrol is less likely to do so. The daily dosage of each is 0.5 to 5 mg. given by mouth in tablet form, or by injection. Subcutaneous implantation of 60 mg. œstradiol tablets is also effective. Some patients will respond to a daily dosage of 0.5 mg. and the smallest effective dose should be used. In any case the dose should be reduced gradually to avoid "withdrawal bleeding," and therapy should not be continued longer than necessary. The œstrogens, however, are not dangerous drugs, and there is no reason to believe that they are carcinogenic in woman. Sedatives, such as bromides, or phenobarbitonum, are also useful.

Adiposity is more refractory to treatment, which should be on the general lines indicated in another section. Hirsutism is not amenable to hormone therapy, but fortunately it is rarely of any severity.

SEXUAL PRECOCITY

Synonyms.—*Pubertas Præcox*; *Macrogenitosomia*.

Definition.—The attainment of sexual maturity in childhood some years before the normal time of puberty.

Ætiology and Pathology.—Sexual precocity may be due to a variety of causes, which ultimately belong to one of three groups, primary gonadal; primary adrenal; primary pituitary or hypothalamic-pituitary. Thus the underlying lesion may be an adenocarcinoma of the testis, a granulosa cell tumour of the ovary, an adenoma or adenocarcinoma of the adrenal cortex, a pineal tumour (which acts pathologically by mechanically stimulating the hypothalamic pituitary mechanism and not by producing any specific hormone of its own), encephalitis, internal hydrocephalus, or a third ventricle tumour. There is also an idiopathic familial type of sexual precocity. Whatever the mechanism, the result is a hypersecretion of androgenic or œstrogenic hormone.

Symptoms.—In boys, the sexual precocity is shown by enlargement of the penis and sometimes of the testicles, development of hair on the pubis and to some extent on the face, and often considerable strength. The latter, vividly described as the *Heracles type*, was thought to be characteristic of adrenal tumours, but may also occur with hypothalamic or third ventricle tumours. The boys will show obvious sexual behaviour, even running after and attacking adult women, masturbating against their legs, which they may clasp with great strength and may bite with anger if frustrated. Seminal emission is rare, and fertilisation not recorded. The precocity may begin in very early childhood.

With girls, there are clinically two main types. When the condition is due to ovarian hyperactivity, either primary or secondary to a hypothalamic-pituitary stimulus, it is manifested by qualitatively normal sexual development, pubic hair, well-formed breasts, menstruation, and even pregnancy, the last having been recorded as early as 6 years of age. With adrenal tumours, menstruation is usually absent, the clitoris is enlarged, the voice is deep,

and hirsutism occurs on the face and body, as in virilism. These manifestations are due to the secretion of androgenic hormone by an adrenal tumour.

In both sexes, the sexual maturity is associated with premature dentition, and early union of the epiphyses. Rapid growth occurs, both with pituitary and adrenal tumours. Although the instincts may be adult, the intellectual activity usually corresponds to the chronological age.

Diagnosis.—In girls, an enlarged clitoris and hirsutism suggest an adrenal tumour, whereas homosexual precocity, without hirsutism, may be due to an ovarian granulosa cell tumour, or, more commonly, bilateral adult development of the ovaries, or multiple cystic ovaries. Although, in the two latter instances, the initial stimulus is probably a pituitary one, there is often no gross detectable pituitary or hypothalamic pituitary lesion. In boys with an adrenal tumour, the testes remain infantile, although the penis is big, whereas with a primary pituitary, or hypothalamic-pituitary lesion, the testes tend to be developed to adult size and function. Pineal tumours may be manifested by ocular palsies, papilloedema, somnolence, and other hypothalamic features such as polyphagia, adiposity, diabetes insipidus, and disturbances in temperature. Precocious puberty may also occur with third ventricle tumours, aqueductal block following encephalitis lethargica, tuberculous or syphilitic meningo-encephalomyelitis, post-measles encephalomyelitis, supra-sellar tumours, neoplasms involving the floor of the third ventricle, and tumours of the mamillary bodies and tuber cinereum. Ventriculograms and exploratory cranial operations may be necessary.

Prognosis.—Idiopathic or familial sexual precocity may proceed to a normal adult state. Adrenal and testicular tumours are usually malignant, whereas ovarian tumours are generally not so. Intracranial lesions may be mechanically fatal. Removal of adrenal or gonadal tumours tends to produce a reversion to normal in the absence of metastases.

Treatment.—This depends on the possibilities of surgical removal of an adrenal, testicular, or intracranial neoplasm when present. In idiopathic or hypothalamic-pituitary cases in the male, oestrogens may control sexual behaviour.

S. L. SIMPSON.

SECTION VIII

DISEASES OF THE DIGESTIVE SYSTEM

DISEASES OF THE MOUTH

ORAL SEPSIS¹

ORAL sepsis is the condition in which excessive bacterial activity occurs in the mouth. Apart from actual infection associated with the teeth and gums, it develops whenever insufficient attention is paid to the cleanliness of the mouth. Thus particles of food may stagnate between the teeth, under bridges, and in connection with badly fitted dental fillings, crowns and plates which are not removed and washed with sufficient frequency.

The mouth should be thoroughly examined in every patient, from whatever condition he may be suffering, but with special care in all digestive disorders and in those conditions which will be presently described as possible sequels of oral sepsis, even if the patient says he has never suffered from toothache and that he regularly visits his dentist. In patients who wear tooth-plates the mouth should be examined both before and after their removal. Each tooth and the gum surrounding it should be carefully inspected. The presence of tartar and red swollen gums indicates that some infection is present. In doubtful cases the patient should be sent to a dentist for an expert opinion, and if no obvious disease is found, radiographs should be taken, as they alone can show with certainty the existence of septic foci under apparently well-fitting crowns and fillings and at the roots of teeth which are otherwise perfectly healthy, and they make it possible to determine with great accuracy the extent of any periodontal infection.

DENTAL HYGIENE

Dental sepsis does not occur if the teeth are always kept free from food between meals. The teeth should be thoroughly cleaned every morning and evening by brushing in one direction only—from the gums towards the teeth. Normally the gums completely fill the spaces between the teeth, but when they begin to recede, the spaces are no longer filled and food collects between the teeth. As this food cannot be removed by a tooth-brush, the brushing must be followed at night by the use of a metal tooth-pick, bent at an angle so that it will pass readily between the molar teeth. Patients with inflamed gums or pyorrhœa should use wooden instead of metal tooth-picks so as to massage the gum papillæ as well as clear the spaces. They should also massage the gums with the forefinger and thumb from the gum towards the teeth after using the brush, and the dried gum margin should be painted

¹ I am indebted to Mr. A. L. Spencer-Payne for help in revising this section.

with tincture of iodine applied on a small swab of wool held by curved dental tweezers.

Artificial teeth should be kept in antiseptic at night, and should be thoroughly scrubbed with a brush and soap and water, if possible after every meal.

Children should be given some food at each meal which requires thorough mastication. Soft food, which can be swallowed without chewing and with the production of little or no saliva, is likely to cause stagnation of sticky carbohydrate material between the teeth. Mouth-breathing should be corrected by direct treatment of nasal obstruction and by respiratory exercises.

At the end of every meal some fluid should be drunk, or some fresh fruit, the acid of which excites the flow of saliva, should be eaten in order to keep the teeth clean.

The dentist should be visited twice a year, even when there is no reason to suppose that anything is abnormal, so that tartar can be removed, early caries dealt with, and pyorrhœa alveolaris recognised and treated in its earliest stage.

(1) PYORRHOEA ALVEOLARIS; CHRONIC PERIODONTITIS

Ætiology and Pathology.—Stagnation of food mixed with pyogenic organisms between the teeth leads to inflammation of the edge of the gums—marginal gingivitis. The attachment of the muco-periosteum to the neck of the tooth is destroyed, and a pocket develops between the tooth and the gum. The margin of the alveolar process is then slowly eroded as a result of rarefying osteitis, until it may finally be replaced by granulation tissue. Stagnation of infective material in the pocket leads to gradual extension of the disease and aggravation of the gingivitis. Pus is produced, the condition at this stage being commonly known as pyorrhœa alveolaris.

Symptoms.—In marginal gingivitis the edge of the gum of one or more teeth is red and swollen and bleeds with abnormal ease when brushed, the first part to be affected being usually the interdental papillæ. When pyorrhœa alveolaris has developed, pockets are present round the teeth, and pus can generally be seen exuding from the edge of the gum. Even when none is seen on first examining the mouth, beads of pus appear if the edges of the gum are pressed. In chronic cases the teeth are often loose. Reflex salivation occurs, and an excessive quantity of mucus is secreted by the small mucous glands of the mouth. This is a common cause of aërophagy. The accumulation of decomposing food, debris and pus in the pockets round the teeth produces an unpleasant taste in the mouth, most marked on waking in the morning, and is a common cause of foul breath. There is no pain, and the slight discomfort which may be present is generally insufficient to induce the patient to consult a dentist.

Treatment.—In early cases the disease can be arrested by sealing and treatment of the pockets with strong antiseptics. When the supporting bone has been destroyed to more than half the depth of the root, extraction is necessary. In intermediate cases the gum should be cut away in order to eradicate the pockets. The patient should then be given detailed instructions regarding oral hygiene (*vide supra*).

(2) DENTAL CARIES

Ætiology and Pathology.—Foods containing relatively abundant vitamin D promote the calcification of teeth, whilst cereals, especially oatmeal, contain a substance which hinders calcification. When vitamin D is abundant in the diet its calcifying power is strong enough to counteract the effect of cereals and of a relative deficiency of calcium. Dental caries occurs when the diet is deficient in vitamin D, especially when this is associated with excess of cereals or deficiency in calcium. Though the above views are universally accepted in England and America, extensive and accurate observations in India have shown that natives living on ill-balanced diets containing little or no fruit, green vegetables and milk, with a very inadequate supply of vitamins A, C and D, have little caries, though they are very undernourished and often rickety. The percentage of carious teeth in children in Kangra was 6 compared with 57 in Rochester, N.Y., and of caries-free children was 4 per cent. compared with 0.2. It seems clear that the absence of eating between meals, the consumption of natural unrefined foodstuffs and the almost complete absence of sugar with production of organic acids by fermentation are of much greater importance than vitamin deficiency in the development of caries.

Symptoms.—Carious teeth are tender, and their presence renders mastication painful. The patient therefore avoids using the affected teeth, and this favours the deposit of tartar and the stagnation of food. If many teeth are affected the food is bolted, so that indigestion is likely to occur owing to insufficient mastication, quite apart from possible infection of the alimentary canal caused by swallowing septic material from the mouth. The irritation produced by the decomposition of stagnant food around the teeth gives rise to marginal gingivitis and pyorrhœa alveolaris. Oral sepsis produced in this way is of much more importance than that caused by the caries itself, as the quantity of decomposing material and bacteria swallowed from dental cavities is comparatively small, and no local absorption of toxins or bacteria can occur so long as the pulp cavity is not reached. When the latter becomes infected, absorption of toxins is likely to lead to enlargement of the cervical glands, especially in children, and the chronic inflammation produced in this way is a common precursor of tuberculous infection of the glands, and probably also predisposes to lymphadenomatous changes. Inflammation of the pulp spreads to the periodontal membrane and may finally produce an alveolar abscess.

Dental caries is the most common cause of toothache, and pain is often referred to various situations more or less remote from the teeth.

Treatment.—A relatively high vitamin D content of the food can do much to diminish the incidence of caries in children if the vitamin is given during the development of the teeth; a beneficial effect may be obtained if it is given at a fairly late stage of development; and even when it is given after the eruption of the teeth the onset and spread of caries is delayed. It seems likely, however, that prohibition of eating between meals, the greater use of natural unrefined vegetable foods and the elimination of sugar from the diet would have a greater effect on the incidence of rickets.

Dental cavities produced by caries should be filled at the earliest possible moment, but if this cannot be efficiently done the teeth should be extracted,

as tender teeth which prevent proper mastication are a much greater source of danger than the absence of teeth, even in very young children. Removal of all the milk-teeth in children may cause narrowing of the dental arch and consequent crowding of the permanent teeth, but this can be easily remedied by treatment, whereas the septic condition of the mouth caused by extensive caries may lead to permanent ill-results.

(3) APICAL INFECTION

Ætiology.—Infection of the apex of the root of a tooth can occur only if the pulp is dead, except in rare cases of extensive caries.

Symptoms.—Apical infection may be acute or chronic. In the former an alveolar abscess forms, which gives rise to the usual symptoms and signs of inflammation. Chronic apical infection, on the other hand, frequently gives rise to no pain or discomfort, and no signs recognisable on ordinary examination. It can then be recognised only in a good radiograph.

Treatment.—In cases of moderate severity the pulp canal should be opened and sterilised with ammoniacal silver nitrate followed by formalin, or by ionization with zinc chloride, and the root should be filled to its apex with an impervious material. In more advanced cases, and in all in which secondary symptoms are present, extraction should be performed without delay and the socket should be curetted.

RESULTS OF ORAL SEPSIS

The inflamed condition of the gums often leads to general stomatitis and sometimes to chronic pharyngitis and tonsillitis. Infection of teeth in the upper jaw may spread directly to the antrum and lead to sinusitis. Inhalation of septic material from the mouth may lead to infection of the bronchi and lungs, the danger of pulmonary complications after general anaesthesia being greatly increased if the mouth is in a septic condition. Chronic bronchitis and bronchiectasis often improve rapidly when oral sepsis is overcome.

Most of the pus which is constantly forming round the teeth in pyorrhœa alveolaris is swallowed. The amount is often considerable, as the ulcerated area round each tooth may be as great as half a square inch. During the day the infected pus is so diluted by what is eaten and drunk that it cannot do much damage, most of the bacteria being destroyed by the hydrochloric acid in the stomach. During the night, however, when no hydrochloric acid is secreted and nothing is eaten or drunk, the pus and organisms which are constantly swallowed with the saliva may infect the stomach and intestines. Pyorrhœa alveolaris is thus an important factor in the production of chronic gastritis, especially in individuals with hypochlorhydria and achlorhydria, and it may help to prevent the healing of a chronic gastric or duodenal ulcer. The danger of infecting the small intestine and, through it, the colon, and of ascending infection of the gall-bladder and appendix is greatly increased in the absence of the normal bactericidal action of the gastric juice in achlorhydria.

The local reaction in pyorrhœa and in apical infection may be sufficient to prevent the passage of toxins and organisms into the circulation. In many cases, however, toxins are absorbed. Non-hæmolytic streptococci are found

in the blood immediately after the extraction of teeth in 75 per cent. of cases if chronic gum infection is present, and less frequently with apical infection. The trauma caused by "rocking" a tooth during its removal increases the liability to a severe degree of bacteriæmia. The bacteriæmia generally lasts only ten minutes, but occasionally subacute streptococcal septicæmia follows, and, if the heart valves are already abnormal, subacute infective endocarditis may develop.

Apart from bacteriæmia the toxæmia caused by chronic dental infection may give rise to general ill-health, which may be accompanied by septic anæmia and slight chronic pyrexia. The importance of oral sepsis in the pathogenesis of rheumatoid arthritis, fibrositis, neuritis, and iridocyclitis has been much exaggerated, but it may aggravate these conditions when they have developed as a result of other factors. Various disorders of the skin, such as chronic eczema, urticaria, rosacea and erythema, may also occur, and angioneurotic oedema is generally secondary to dental sepsis. The causal connection between these conditions and dental sepsis is shown by their temporary aggravation after an overdose of autogenous vaccine and in some cases after extracting the teeth.

Treatment.—When dental extraction is required in patients with valvular disease of the heart, great care should be taken to eliminate gross infection as completely as possible before the operation, and manipulation of the infected teeth during the extraction should be reduced to a minimum. In any case teeth should not be extracted until pockets have been thoroughly cleansed. With more local infection and in the presence of general disease, 2 grm. sulphonilamide should be given four-hourly for 24 hours, starting six hours before the extraction. If many teeth are infected, three or four should be extracted at intervals of about five days in order to reduce the risk of a severe reaction.

Although the masticatory power of artificial teeth is only about one-fifth of that of normal teeth, indigestion is unlikely to result if care is taken to avoid tough meat and hard food. Even in the absence of artificial teeth no disturbance of digestion follows if only soft food is eaten. Many people, however, especially among the very poor and ill-educated, continue to eat ordinary food in spite of being edentulous or having only a few septic stumps which are useless for chewing. Hard masses of food then reach the stomach, where they are broken up by the churning movements in the pyloric end of the stomach. This is an important exciting cause of chronic gastritis and chronic gastric ulcer, and consequently a remote cause of carcinoma of the stomach. It is probably the main explanation of the relatively high incidence of the latter in the poor compared with the well-to-do.

STOMATITIS

CATARRHAL STOMATITIS

Ætiology.—Catarrhal stomatitis is common in ill-nourished children during dentition and in association with gastro-intestinal disturbances. In adults it may result from excessive consumption of alcohol or highly-seasoned food, or excessive smoking. It is sometimes present in the specific fevers,

and may also be caused by septic teeth and a dirty or badly-fitting plate. It develops rapidly in very ill people whose mouths are not kept clean, especially if they sleep with the mouth open.

Symptoms.—The gums and lips are often affected alone. In other cases the whole mouth, including the tongue, is involved. The mucous membrane is red and dry, but excess of mucus may be secreted by the small buccal glands. The tongue is swollen and furred.

The mouth is uncomfortable, and occasionally actual pain is present, especially on mastication. The patient complains of a nasty taste, especially on waking, and fetor oris may be present. The general health is unaffected.

Treatment.—The teeth should be cleaned with special care, and the tongue kept as free as possible from fur by scraping. A mouth-wash should be used after each meal, and glycerin of borax should then be applied to the inflamed parts.

ULCERATIVE STOMATITIS

Ætiology.—Ulcerative stomatitis is not a specific disease, but is, like catarrhal stomatitis, produced by the action of various irritants. It can develop from neglected cases of catarrhal stomatitis, and is a prominent symptom of mercurial poisoning and scurvy. The following are special varieties of the condition.

(a) RECURRENT ULCERATION IN ADULTS.

Single or multiple superficial ulcers may occur on the mucous membrane of the cheeks, lips, tongue and gums. They have a grey surface with a red, but not raised, border, and the intervening mucous membrane is generally healthy. In severe cases, however, the ulcer is deeper and its base bright red. Each ulcer generally lasts only a few days, but a patient may have one or more in his mouth for months, or even years, without an interval. They are often very painful, especially on chewing, and they may make it impossible to take any acid food. Their ætiology is most obscure; the condition is aggravated by oral sepsis and ill-fitting plates, and some ulcers may begin as abrasions produced by the careless use of a tooth-brush, but it appears to depend primarily upon some obscure constitutional defect. It is not associated with any disturbance in digestion or with any special form of gastric secretion. The saliva is not acid and the ulcers do not appear to be infective in origin.

No treatment beyond scrupulous attention to oral hygiene and the application of silver nitrate to each ulcer as it appears is, as a rule, of any use. A severe recurrent case, associated with colitis, in a girl of seven, completely recovered after adding liver to her diet. Cures have been reported from the use of nicotizamide, 100 mgm., three times a day for a month.

(b) APHTHOUS (OR VESICULAR) STOMATITIS.

Ætiology.—Apthous stomatitis occurs especially in children under three, either alone or associated with some febrile or digestive disorder.

Symptoms.—The aphthæ consist of small slightly raised vesicles, each surrounded by a red areola. Within 24 hours the vesicles rupture, leaving grey ulcers, 2 to 4 mm. in diameter, with bright red margins. The ulcers heal rapidly. They occur especially on the inner surface of the lips, the edges of

the tongue and the inside of the cheek. In severe cases the pillars of the fauces may be affected. The mouth feels sore, and the child is unwilling to take food. Salivation is frequently present.

Treatment.—The mouth must be carefully washed after meals with potassium chlorate solution (10 grs. to 1 fl. oz.). In severe cases the ulcers may be treated with silver nitrate.

(c) FOLLICULAR STOMATITIS.

Ætiology.—Follicular stomatitis may occur at any age, but especially in nursing women.

Symptoms.—The mucous follicles of the lips and cheeks become inflamed and swollen; the epithelium over them breaks down, and ulcers, 3 to 5 mm. in diameter, result. They may cause no symptoms, but more commonly they give rise to a considerable amount of pain on taking food and to reflex salivation.

Treatment.—The ulcers heal rapidly after being touched with silver nitrate.

(d) MERCURIAL STOMATITIS.

Vide pp. 228 and 403.

(e) ULCERO-MEMBRANOUS STOMATITIS.

Ætiology and Pathology.—Severe ulcer-membranous stomatitis is a contagious disease, which occurred in epidemic form among the troops in England and France during the War of 1914–1918, and it is by no means rare in civilians. It appears to be caused by infection with the same spirilla and fusiform bacilli which cause Vincent's angina.

Symptoms.—All parts of the mouth and pharynx may be involved, but the margins of the gums are specially liable to be affected. The stomatitis is similar to that caused by mercury, and the gums may be so swollen and bleed so readily that scurvy is simulated. The breath has a characteristic fetid odour, and the tender gums may make mastication painful.

The disease is sometimes acute, but more often runs a chronic course and is often followed by pyorrhœa alveolaris. It generally gives rise to but little constitutional disturbance.

Treatment.—The pockets and interdental spaces should be packed with a paste of zinc oxide and cloves on strands of cotton-wool, which is left for at least a week. After removal the teeth should be sealed and any suspicious areas treated by the application of 10 per cent. chromic acid for one minute followed by hydrogen peroxide kept in the mouth for two minutes. The patient should be given 300 mgm. vitamin C daily for a fortnight, followed by 50 mgm. daily for six months. Sodium perborate should be used as a tooth-powder and hydrogen peroxide as a mouth-wash. Smoking should be forbidden.

(f) GANGRENOUS STOMATITIS.

Synonyms.—Cancerum oris; Noma.

Ætiology.—This rare disease occurs in children, especially girls between the ages of two and five, who live under very insanitary conditions. It

generally develops during convalescence from an acute fever, especially measles, and less frequently scarlet and typhoid fever. It also forms part of the clinical picture of agranulocytosis (p. 832).

Symptoms.—A sloughing ulcer develops in the inside of the cheek or on the gums; it rapidly spreads and leads to brawny induration of the skin of the cheek. Occasionally it heals spontaneously, but more frequently it perforates the cheek or spreads to the tongue, chin, jawbone or eyelid and eye.

Cancrum oris is accompanied by severe constitutional symptoms, the patient being prostrated with a high temperature and rapid pulse. Diarrhoea or broncho-pneumonia frequently follows, and death generally occurs between seven and ten days on the onset.

Treatment.—The only adequate treatment for cancrum oris in children is to destroy the diseased part as completely as possible with the cauterizer. For the treatment of agranulocytosis *vide* p. 833.

THRUSH

Ætiology.—Thrush is most common in weak, emaciated infants with gastro-intestinal symptoms, who have been fed with an unsuitable diet, and whose mouths have not been kept clean. Acid fermentation of food remnants leads to catarrhal stomatitis, and this is likely to be followed by thrush. Thrush occurs in epidemic form in badly-managed institutions, being spread by dirty feeding-bottles. The disease may also occur in enfeebled adults in the late stages of tuberculosis, cancer and diabetes, and in severe febrile infections.

Pathology.—Thrush is caused by infection with *Oidium albicans*—a fungus, the filaments of which form a dense felt-work in the superficial epithelial layer of the mucous membrane.

Symptoms.—Thrush generally appears first on the tongue, and then on the cheeks, lips, hard palate, tonsils and pharynx. In rare cases the entire buccal mucous membrane is covered, and the infection may even spread to the vocal cords, œsophagus and stomach. It begins as slightly raised, pearl-white spots, which gradually grow and then coalesce. The white material can be readily detached, leaving either intact mucous membrane, or, in more severe cases, a bleeding and ulcerated surface.

Diagnosis.—Adherent milk curds may superficially simulate thrush. In aphthous stomatitis the white patches are at first vesicles and then definite ulcers, and salivation is present in contrast to the dry mouth in thrush. A definite diagnosis can be made only with the aid of the microscope.

Treatment.—Thrush should be prevented by keeping the mouth clean and babies' bottles sterilised. It is important to improve the patient's general health as well as to give local treatment. The mouth should be washed with sodium sulphite solution (60 grs. to 1 fl. oz.), after which the fungus can be easily scraped off.

DISEASES OF THE SALIVARY GLANDS

PTYALISM

Ætiology.—The flow of saliva is increased by reflexes originating in the mouth and also in more distant situations. Thus all pathological conditions in the mouth and its neighbourhood, such as stomatitis, epithelioma of the tongue and carious teeth, especially if associated with pain, are accompanied by salivation. Trigeminal neuralgia, whatever its cause, is frequently associated with a reflex flow of saliva. Mechanical irritation of the œsophagus caused by the passage of a tube into the stomach or by the impaction of a foreign body causes salivation, which is a common symptom in achalasia of the cardia and in simple and malignant ulceration of the œsophagus. Reflex salivation is the cause of waterbrash associated with the hyperchlorhydria of duodenal ulcer.

The salivation which may occur during menstruation and in the early months of pregnancy is also probably reflex in origin. Salivation is a common and sometimes very distressing symptom of paralysis agitans and post-encephalitic parkinsonism. Ptyalism may result from excessive smoking. It is also caused by the specific stimulating action of certain drugs, such as pilocarpine, and by drugs such as the iodides and mercury, which are partially excreted by the salivary glands.

Symptoms.—Every time saliva is swallowed air passes with it into the stomach. In neurotic individuals a spitting or swallowing tic may develop; the latter is always accompanied by aerophagy and the patient consequently complains of severe flatulence with excessive belching (p. 604). Salivation may also cause waterbrush (p. 601).

Treatment.—In order to cure ptyalism the primary cause must be discovered and removed. As purely symptomatic treatment, belladonna should be given: 5 minims of the tincture, taken three times a day, half an hour before meals, is sufficient in the majority of cases, but occasionally much larger doses are required. The drug has the additional advantage of diminishing the secretion of gastric juice when gastric hypersecretion is the primary cause.

XEROSTOMIA

Ætiology.—The dry mouth, which is constantly present in fevers, is due mainly to deficiency in the psychical, chemical and mechanical stimuli to salivary secretion. The associated toxæmia probably also exerts some direct inhibitory action on the gland-cells. Depressing emotions and the loss or perversion of taste, which may occur when the tongue is furred, result in diminution in the psychical secretion. The paralysis of the secretory nerve-endings produced by belladonna, stramonium and their alkaloids sets the limit to the dose of these drugs which can be administered. The secretion of saliva is also diminished when excessive quantities of fluid are lost by other channels, as in severe diarrhœa. Diseases of the salivary glands themselves, such as mumps, result in diminished secretion. Severe xerostomia

occasionally develops without any obvious cause. A dry mouth is also a common result of sleeping with the mouth open.

Symptoms.—Deficient secretion of saliva causes the mouth to become dry and septic, as particles of food remain between the teeth, where they undergo bacterial decomposition. The tongue is furred and dry, and there is often an unpleasant taste in the mouth. It is difficult to chew food sufficiently, and the appetite is impaired as a result of the condition of the mouth and the difficulty in tasting. The insufficiently chewed food is likely to irritate the stomach. In severe cases dysphagia occurs and speech becomes difficult. The loss of the digestion of starch by the ptyalin of the saliva is of no importance owing to the amylolytic activity of the pancreatic juice.

Treatment.—A diet should be chosen which stimulates the flow of saliva; acids are most active, then salt and bitters, whilst sweet substances have very little action. The food should be given in as appetising a form as possible and masticated very thoroughly. If the saliva is only slightly deficient, dry biscuits should be taken at each meal. The taste of a bitter mixture taken immediately before meals may directly stimulate the flow of saliva, and pilocarpine may be tried, but it is rarely of much use, as a dose sufficiently large to increase the flow of saliva generally produces unpleasant symptoms, such as excessive sweating. It is, however, valuable in the treatment of paralysis agitans and post-encephalitic parkinsonism, as it counteracts the xerostomia (and also the paralysis of the intrinsic eye muscles) often caused by hyoscine and stramonium, without diminishing their effect on the tremor of paralysis agitans and the rigidity following encephalitis. Great care should be taken to keep the teeth clean, and the mouth should be washed after each meal.

SPECIFIC PAROTITIS (MUMPS)—(see p. 174)

PAROTITIS

Ætiology.—Parotitis is almost always due to infection ascending Stenson's duct from the mouth. This is particularly apt to occur in the acute parotitis that not infrequently follows operations on the alimentary tract, when the mouth has become septic owing to dehydration, the absence of chewing and normal salivation. It may follow obstruction by a stone in Stenson's duct. Subacute parotitis commonly occurs without obvious cause in persons with healthy mouths. Infection presumably ascends in these cases from the mouth, but may occur by direct spread from the tonsils, through the lymphatics draining an infected middle ear, or possibly by blood stream infection. This subacute or recurrent type of infection is relatively common in children and occurs more frequently in women than in men. An ascending infection may be limited to Stenson's duct, not involving the gland itself, and therefore giving rise to a condition of sialodochitis.

Symptoms.—In acute parotitis following operation both glands are generally affected, except in mild cases when the condition is often unilateral. The glands are enlarged and tender, the skin over them stretched and shiny. In severe cases suppuration takes place, the neighbouring lymphatic glands enlarge, the temperature is high and constitutional symptoms are present.

The mouth is dry and difficult to keep clean; the tongue is covered with a thick, dry fur. The mouth of Stenson's duct is everted and forms a small, red nodule from which a bead of pus can sometimes be squeezed. In milder cases the inflammation gradually subsides; rarely the condition becomes chronic, the parotid glands remaining permanently enlarged and secreting no saliva.

In the subacute form swelling of one or both glands may occur on a single occasion or repeatedly at intervals of weeks or months, sometimes over a period of many years. The swelling usually lasts for several days, but may persist for months. Fluctuation in the size of the swelling takes place, an increase usually accompanying or following mastication. The inflamed gland is painful to touch and the overlying skin may be reddened and hot. Firm pressure over the gland often causes expulsion of pus or turbid saliva from the reddened orifice of Stenson's duct. In recurrent cases the saliva is clear and free from debris between attacks. X-ray examination of the ducts after injection of lipiodol frequently shows bead-like dilatation of the terminal acini. In severe cases there may be irregular dilatation of the main and branch ducts.

Microscopical examination of the parotid saliva shows degenerated leucocytes, epithelial cell debris, and organisms. Streptococci and pneumococci are most commonly found.

Treatment.—The mouth should be kept clean with the greatest care and the flow of saliva promoted by means of chewing gum. In the acute cases, if suppuration occurs, the gland must be incised. In subacute cases, firm massage over the parotid swelling from the ear towards the angle of the mouth, especially at meal times, assists drainage. Local application of heat relieves pain and congestion. In chronic cases, the injection of 1 per cent. mercurochrome into the duct has proved helpful. Deep X-rays are also of value in chronic cases, but should be employed with care in the case of children.

NON-INFECTIVE RECURRENT SWELLING OF THE PAROTID GLANDS¹

Ætiology.—This condition may occur at all ages. Its pathogenesis is unknown, but the frequent association with conditions, such as asthma, hay-fever and eczema, in the patient himself and in his relatives has led to the suggestion that an allergic process may sometimes be responsible. This theory is supported by the presence of eosinophil cells in the parotid saliva of some cases.

Symptoms.—Eating may precipitate attacks, especially when the food is acid in character, and in some patients the parotid glands become swollen whenever food is taken over a period of years. Exposure to cold sometimes has the same effect. The swellings are more often bilateral than unilateral. They develop rapidly and are present for a short time only, often subsiding within half an hour and seldom persisting for more than 24 hours. Single isolated attacks may occur, but owing to their brief duration and the absence of after-effects they are seldom seen, and cases presenting themselves for treatment are usually recurrent. Signs of inflammation are absent, the parotid saliva contains no pus, and the swellings are seldom painful.

¹ I am indebted to Dr. R. S. Bruce-Pearson for this article.

In most cases secretion can be expelled from the parotid duct by pressure during the attack. Globules of jelly-like mucus obstructing Stenson's duct may first be forced out, followed by 2 or 3 c.c. of clear saliva. It is in this type of case that eosinophil cells have been observed both in the mucous plugs and in the pent-up secretion. This is sterile and contains no pus, but secondary infection may supervene in patients in whom swellings have recurred over a long period. In early cases saliva may be difficult to obtain.

Sialography may show gross fusiform dilatation of the main and branch ducts in long-standing cases, but in slight and early cases there may be no abnormality. Infective and epidemic parotitis and obstruction by a stone in Stenson's duct must be excluded before a definite diagnosis is made.

Treatment.—Massage over the gland is of value, especially when mucous obstruction is present. In some cases injection of adrenaline subcutaneously leads to subsidence of the swelling.

UVEO-PAROTID SYNDROME¹

Definition.—In the uveo-parotid syndrome, enlargement of the parotid glands is associated with uveitis and facial paralysis and sometimes with lesions of other cranial nerves and a slight intermittent pyrexia.

Pathology.—The uveo-parotid syndrome is probably a special expression of that form of reticulo-endotheliosis, known as sarcoidosis. Cases have been described in which the uveo-parotid syndrome has been found associated with the skin, pulmonary and bone lesions characteristic of sarcoid. The tuberculin skin reaction is frequently negative, but a number of cases have come to autopsy in which miliary tuberculosis has been the cause of death. Sections of the parotid gland and iris removed during life show granulation tissue of fibrosing type with epithelioid and giant cells but little or no tendency towards caseation. The appearance of the nodules which occur on the iris in about a third of the cases is said to be characteristic of tuberculosis if syphilis and leprosy are excluded. It seems certain that at least one group of cases is tuberculous.

Symptoms.—The essential features are swelling of the parotid glands and inflammation of the uveal tract. In about half the cases there is in addition facial paralysis on one or both sides. Swelling of the lachrymal, submaxillary or sublingual glands is sometimes present, lymph glands may be generally enlarged, and the spleen may be palpable. Peripheral neuritis with loss of vibration sense, paræsthesia, anæsthesia, weakness of the limbs, and absent knee and ankle jerks, and paralysis of the cranial nerves other than the seventh have been described. Some fever is frequently present.

The parotid swellings are almost invariably bilateral, though one side may precede the other. They are firm and painless, often nodular, and sometimes confined to one part of the gland. They do not vary in size with the secretion of saliva. The orifices of Stenson's ducts and the sialographic appearance of the ducts are normal. The parotid saliva is clear, but may be diminished, leading to dryness of the mouth. The uveal lesions most commonly take the form of iridocyclitis, but choroido-retinitis and optic neuritis may be present; vitreous hæmorrhages have been described, and glaucoma

¹ I am indebted to Dr. R. S. Bruce-Pearson for this article.

and cataract may develop. Skin lesions, including erythematous rashes, indurated erythematous patches on the extremities, and erythema nodosum occur in approximately 20 per cent. of cases. Some of these lesions are almost certainly due to skin sarcoid.

Diagnosis.—In the presence of bilateral uveitis, with swelling of one or both parotid glands, the diagnosis is not difficult. In some cases, however, the uveitis or parotid swellings may precede one another by an interval of some weeks. In the latter case subacute parotitis can be excluded by the absence of tenderness over the gland and of pus cells in the parotid saliva. Cases in which there is swelling of the lachrymal glands fall into the group included in the Mikulicz syndrome. A radiograph of the thorax occasionally reveals evidence of tuberculosis, or the nodular deposits of sarcoid. The small bones of the hand may also show the radiological appearance ("shot holes") of the latter.

Prognosis.—The parotid swelling, uveitis and nerve palsies usually undergo apparently spontaneous cure in the course of some months or even after a period of two years. Recurrences may occur, either of the original lesion, of sarcoid elsewhere in the body, or of frank tuberculous infection. The uveitis is often followed by the development of posterior synechiae, and vitreous opacities giving rise to impairment of vision are not uncommon. The facial palsy almost invariably recovers completely. In a small proportion of cases death resulted from tuberculosis.

Treatment.—General treatment as for tuberculosis, and the usual treatment of uveitis should be adopted. Tuberculin injections are dangerous on account of the severe focal reactions that may follow. Deep X-ray treatment of the parotid glands has been employed successfully.

ARTHUR HURST.

DISEASES OF THE TONSILS

ACUTE TONSILLITIS

Tonsillitis has been classified as superficial, follicular or lacunar, and parenchymatous, according to the degree in which the various parts of the gland bear the brunt of the inflammation; the distinction, however, is not a definite one, as the entire organ is necessarily inflamed.

Ætiology.—The disease is rare in children below the age of 5 or 6, and after middle age; and it is commonest in spring and autumn. It is predisposed to by general ill-health, overwork and a polluted atmosphere; the escape of sewer-gas from defective drains is a probable cause, and the infection may be carried by water or milk. It occurs as a regular symptom of scarlet fever, measles and diphtheria. There is a very close connection between rheumatism and tonsillitis, and it was formerly believed that tonsillitis was of rheumatic origin; but it is now generally recognised that both acute rheumatic fever and chronic rheumatic pains in joints and muscles are frequently caused by septic infection through the tonsils. Unhealthy conditions of the tonsils due to previous inflammation strongly predispose to further attacks

by causing adhesions in the crypts or supratonsillar fossæ, and between the tonsils and the pillars and plicæ, thus promoting the retention of secretion ; previous partial removal acts in the same way.

Symptoms.—The symptoms are those of a feverish attack, together with a sore throat ; the former often appears before the latter, and only examination of the throat reveals the cause of the disturbance. The temperature may rise to 103° or 105° F., and there is a variable degree of malaise, backache, headache and pain in the limbs. The soreness of the throat radiates to the ear, and is increased by attempts to swallow ; the voice becomes thick, the breath foul, and the submaxillary and upper cervical glands are tender and swollen.

The tonsils are swollen, and their purple-red colour extends to the pharynx, palate and uvula—the latter frequently being œdematous. In the follicular type the surface of the tonsils is spotted over with yellowish masses of secretion which have exuded from the crypts ; sometimes this secretion becomes confluent on the tonsils and occasionally, though rarely, it spreads beyond their surface—it is soft and readily wiped away. The tongue is coated, and the fauces covered with tenacious mucus. There is usually constipation, and the urine is scanty and high-coloured, but not ordinarily albuminous. Albuminuria is, however, an occasional complication, as are pericarditis, endocarditis and suppurative otitis media.

Diagnosis.—The diagnosis from diphtheria is important, and sometimes difficult. The latter is more gradual and asthenic in onset, with less pain, less fever and a more rapid pulse, and the urine frequently contains albumin. The membrane of diphtheria is greyish-white rather than yellowish, and frequently spreads to the pillars and soft palate ; whereas the exudation of tonsillitis rarely spreads, and never to any great extent, beyond the surface of the tonsils. The diphtheritic membrane is adherent and, when detached, leaves a raw bleeding surface, while that of tonsillitis is readily removed and more often discrete. In cases of doubt a bacteriological examination should always be made, and an injection of antitoxin should be given while waiting for the result.

Treatment.—The patient should be kept in bed in a warm well-ventilated room, an initial dose of calomel, 2 to 4 grains, should be administered and followed by a saline aperient. Externally, warmth is usually more comforting than cold, and a hot fomentation applied to the neck and covered by a large pad of cotton-wool gives some relief. Internally, especially if the fauces are clogged with tenacious mucus, a warm alkaline lotion, such as Dobell's solution may be used with advantage, either by means of a spray or a rubber ball-syringe ; but, if the inflammation is so severe that the patient is unable to open the mouth without pain, the lotion should only be used as a mouth-wash ; gargling is, of course, only possible in mild cases. Lozenges containing potassium chlorate, guaiacum or formalin may be employed. Of internal medication, sodium salicylate holds the favourite place in doses of 15 grains every 3 hours, and later three times a day ; or aspirin, 10 grains, may be used instead ; potassium chlorate in 15-grain doses, three or four times daily, appears to be helpful, especially in the follicular variety ; the sulphanilamide group of drugs is of great value, but is not yet to be recommended as the routine treatment of the milder cases. The patient must be encouraged to absorb as much nourishment as his dysphagia permits, and he will usually find that soft semi-solids are easier to

swallow than liquids; there is room for ingenuity and resource in the provision of a suitable diet, such as junket, baked custard, ice-cream, meat jellies and soups thickened with corn-flour or arrowroot. An iron and quinine mixture may be given when the acute symptoms have subsided.

PERITONSILLAR ABSCESS OR QUINSY

Ætiology.—This is an acute affection due to the formation of an abscess outside the tonsil caused by septic secretions in the supratonsillar fossa or in the depths of a crypt bursting through the thin capsule of the tonsil into the surrounding loose areolar tissue. This process is favoured by adhesions obstructing the mouth of the supratonsillar fossa or the crypts, and, therefore, previous tonsillitis and imperfect surgical removal are predisposing causes. The abscess is usually situated above and external to the tonsil, but in rare cases is behind it.

Symptoms.—The affection is unilateral; but sometimes the opposite side is attacked as the first recovers. It begins with a feeling of malaise, fever, often a rigor, and severe pain radiating from one side of the throat up to the ear and into the neck; the cervical glands are enlarged and tender, and the neck stiff. Dysphagia is intense, the tongue thickly coated, and the breath foul. The mouth cannot be opened widely, and a good light is required for examination, when the typical large deep-red swelling is to be seen bulging one side of the soft palate. Pus forms in 2 to 4 days and, if left alone, will eventually burst, usually through the soft palate; relief is then immediate, but occasionally the opening closes prematurely and the abscess refills.

Complications.—Although one of the most painful and distressing of acute diseases, complications are uncommon, and death is very rare; it has occurred from rupture of the abscess, and inspiration of the pus, during sleep. Severe hæmorrhage may take place after spontaneous or surgical evacuation of the abscess when, as the blood may come from the internal carotid or from a branch of the external carotid artery, ligature of the common carotid is called for. The swelling has been known to spread to the larynx, and to necessitate tracheotomy. Suppuration of the cervical glands is a rare complication, as are pneumonia, septicæmia and pyæmia.

Treatment.—The general treatment is the same as that of severe acute tonsillitis, and the pain sometimes calls for an occasional injection of morphine. Pus is probably present as soon as the swelling has assumed a well-defined rounded form, still more so if there is a boggy area in the centre. The abscess should be opened without delay, for this cuts short the attack and diminishes the risk of complications; but it does not always give immediate complete relief when there is marked cellulitis of the surrounding tissues. After the application of cocaine, a narrow sharp-pointed knife is introduced with the cutting edge upwards and the blade held in the sagittal plane; it is made to puncture the swelling at its most prominent part, and to enlarge the incision by cutting upwards as it is withdrawn. The knife should not be passed to a depth exceeding about $\frac{1}{2}$ inch; if pus is not struck, a sinus-forceps is introduced into the wound and pushed backwards until the pus is found, when it is opened widely to assist the evacuation. After the disease has subsided, removal of the tonsil is advisable, in order to prevent recurrence.

CHRONIC TONSILLITIS

Chronic inflammation of the tonsils may, from the clinical point of view, be divided into two groups: Chronic Parenchymatous Tonsillitis or "enlarged tonsils," and Chronic Follicular Tonsillitis.

CHRONIC PARENCHYMATOUS TONSILLITIS

Enlarged tonsils in children are nearly always associated with adenoids; but adenoids are often found in children whose tonsils are not enlarged.

Ætiology.—This is similar to that of adenoids. The condition occurs chiefly in children between the ages of 5 and 15; but it frequently persists into adult life, although normal healthy tonsils atrophy about puberty and hypertrophy seldom takes place *de novo* after that age. The affection may be the result of repeated colds or a sequela of scarlet fever, diphtheria, measles or whooping-cough.

Symptoms.—The symptoms are not easy to separate from those caused by the concomitant adenoids, but it is certain that chronic inflammation of the tonsils can affect the ears, and that gastro-intestinal disturbances and appendicitis are produced by the septic secretion squeezed out of the tonsils during deglutition. Recurrent attacks of acute tonsillitis are common; and the cervical glands are frequently enlarged, may break down and suppurate, or may become tuberculous.

The objective appearances are very various, and it is extremely difficult to estimate the healthiness of a tonsil by inspection. Slightly enlarged tonsils may be prominent and may readily meet on gagging, while big tonsils are often largely buried in the palate or hidden beneath the plica triangularis—in which case a bulging can be seen at the side of the soft palate corresponding to the site of the upper pole.

Treatment.—For children with slight degrees of tonsillar hypertrophy, palliative measures may be tried; an open-air, country life, preferably at the seaside, with cod-liver oil, malt, or iodide of iron, and a nasal lotion for the accompanying adenoids; paints are of doubtful utility, Mandl's solution (iodine, grs. 6, potassium iodide, grs. 12, peppermint oil, min. 3, glycerin, 1 fl. oz.) is perhaps the best.

The tonsils should be removed when there have been repeated attacks of tonsillitis, after a quinsy, when there is chronic enlargement of the cervical glands, and when rheumatic fever or chorea has occurred. Definitely unhealthy tonsils should also be removed in cases of chronic or recurrent otitis media. When chronic cervical adenitis is present, and is not due to some other obvious cause, such as pediculosis or dental caries, the tonsils should be removed whether they appear diseased or not; in these cases about one-third of the tonsils are tuberculous, and this latent tuberculosis cannot be recognised by inspection, many of these tonsils, indeed, being quite small.

The reader is referred to surgical works for details of the operation, but it may be said here that, if a tonsil requires removal, it must be removed completely in its capsule, for the deeper portion of a diseased tonsil is quite as unhealthy as the superficial; trouble in the remaining portion is very common, and the previous operation only adds to the surgeon's difficulties,

In cases where operation is inadmissible, the tonsils may in adults be treated by diathermy, or by application of a caustic, "London Paste," which consists of equal parts of caustic potash and unslaked lime made up into a stiff paste with absolute alcohol. A general anæsthetic is not required, but repeated treatments are necessary, which are not free from pain, and all the tonsillar tissue can only be extirpated by unusual perseverance.

CHRONIC FOLLICULAR TONSILLITIS

In older subjects, when fibrosis has followed the hypertrophy, the stenosed crypts become filled with yellowish-white caseous masses. The patient complains of an offensive taste, foul breath, often of recurrent attacks of sore throat, and of gastric disturbances. Not infrequently various forms of chronic toxæmia, such as fibrositis or arthritis, are induced by absorption from these septic foci. In many cases the tonsils are quite small; they may look healthy, but pus can be squeezed out of the crypts on applying pressure at the anterior pillar by means of a flat instrument.

Treatment.—The treatment in the more marked cases is removal. There are, however, a good many patients who have only a few unhealthy crypts in the tonsils; these may often be cured by passing a fine galvano-cautery point down to the fundus, several applications being usually necessary. The patient may also be shown how to clean out the secretion with a cotton-wool mop on a fine wooden applicator, and to paint the inside of the crypt with Mandl's solution.

VINCENT'S ANGINA

Ætiology.—This affection is believed to be due to two organisms, the bacillus and spirillum of Vincent growing in symbiosis; these organisms may be found in many ulcerative conditions of the mouth and throat, but their constant presence in this affection points to their specific character. The invasion of the throat is frequently secondary to periodontal infection of the gums. It occurs especially in debilitated persons and under insanitary conditions and, though rather rare in civil life, was common during the War of 1914–1918 in some camps and barracks.

Symptoms.—The attack begins insidiously, with malaise, general pains and a temperature of 100° to 101° F. The pain in the throat is slight, but the glands on the affected side become enlarged and tender, and the breath is usually offensive. The affection is nearly always unilateral.

At first there is a patch of soft, yellowish detachable membrane on the affected tonsil which, in a day or two, comes partially away, exposing an ulcer with a well-defined margin. By the end of a week the membrane ceases to form, and the ulcer begins to heal. The ulceration may be quite deep in severe cases, but is ordinarily limited to the tonsil, and very seldom spreads to any distance from it.

Complications are very rare.

Diagnosis.—The disease is particularly interesting by reason of its liability to imitate diphtheria in its early stage, and syphilitic ulceration later. In both cases the discovery of numerous spirilla and fusiform bacilli in smear-preparations—they are difficult to cultivate—will help the physician to the

correct diagnosis ; but these organisms may also be found in tertiary ulceration, and the Wassermann reaction is occasionally positive in Vincent's angina. The subacute onset, the raised temperature and the tenderness of the glands aid the differentiation from syphilis ; and from diphtheria the milder constitutional symptoms, the extremely localised lesion, the soft friable character of the membrane and the absence of the Klebs-Loeffler bacillus.

Prognosis.—Death hardly ever occurs.

Treatment.—Topical application of weak solution of iodine was recommended by Vincent. Liquor arsenicalis and vinum ipecacuanhæ in equal parts, or neoarsphenamine in the strength of 20 grains to the ounce, are effective ; these should be firmly applied on a swab, with due regard to their poisonous nature. Intravenous administration of one of the arsphenamine group of drugs is a valuable measure in the more severe cases. Attention should be paid to the condition of the gums and teeth.

HAROLD S. BARWELL.

DISEASES OF THE PHARYNX

DIVERTICULA (see p. 580)

ACUTE CATARRHAL PHARYNGITIS

This is not a very well-defined affection, and is usually accompanied by acute rhinitis on the one hand, and by laryngitis on the other ; the tonsils also often participate in the inflammation.

Ætiology.—The affection is generally the result of acoryza ; it is also caused by traumatism of any kind and by the irritation of hot fluids, corrosives or chemical vapours, and it forms a part of various acute infectious fevers, such as measles, German measles, scarlet fever, influenza and typhoid.

Symptoms.—The discomfort varies from a tickling sensation, or the feeling of a lump in the throat, to severe dysphagia. The voice is husky and thick, and the cervical glands tender and somewhat enlarged. There is slight fever and general malaise.

The pharynx is to a varying degree red and swollen, especially at the sides behind the posterior faucial pillars, where the swelling forms the so-called "lateral bands." The palate is swollen and relaxed, and the uvula elongated. The posterior wall is often covered by a film of tenacious mucus.

Treatment.—The patient should stay in a warm room and avoid the irritation of smoking, talking, alcohol or irritating foods. Calomel, 2 to 4 grains should be given, and followed by a saline aperient. Aspirin, or sodium salicylate, is helpful, and, as the naso-pharynx is involved, the nose should be syringed with a warm saline lotion which may also be applied to the pharynx as a spray.

ACUTE SEPTIC PHARYNGITIS

This term includes a series of severe infective inflammations, erysipelas of the throat, oedematous, phlegmonous and gangrenous pharyngitis and laryngitis, and angina Ludovici. Any classification must necessarily be a clinical one, based on the severity of the symptoms and their localisation, for they can be produced by a variety of micro-organisms, though they are usually caused by a streptococcus. These severe inflammations are fortunately uncommon, and most often, though by no means invariably, occur in debilitated or alcoholic persons.

Symptoms.—These vary greatly with the severity of the infection, which ranges from a mild inflammation to the most severe septic intoxication. They include malaise, sore throat, dysphagia, hoarseness and dyspnoea. The temperature in some cases rises to 105° or 106° F.; but in many of the worst cases it is hardly raised at all, and may be subnormal. Pleurisy, pneumonia and pericarditis may ensue, or death may result from asphyxia; but the worst cases die from general toxæmia and heart failure, even within 24 hours of the onset of the disease.

The objective appearances, also, are very variable. The pharynx and palate are of a deep purplish-red, and there may be sloughy patches or pseudo-membrane. The entire mucosa may be enormously swollen, and the oedema may involve the upper aperture of the larynx and produce asphyxia. The sublingual region is sometimes occupied by a peculiar brawny swelling, of a hardness like wood, which spreads downwards into the neck to a variable extent, and is known as "angina Ludovici."

Treatment.—The patient must be in bed and well nursed, and every care must be used to ensure that he takes as much nourishment as possible. Poly-valent anti-streptococcic serum is sometimes very successful, and should be given early in a large dose (40 to 50 c.c.). Hot fomentations to the neck and inhalations of steam are comforting. Oedema of the upper aperture of the larynx should be treated promptly by scarification; free incisions should be made with a curved bistoury guided by the finger, and tracheotomy under local anaesthesia must not be delayed, if dyspnoea be severe or not relieved by scarification. For angina Ludovici a deep incision should be made in the middle line, as all anatomical landmarks have disappeared, and an attempt should be made to find pus with the finger or a director. Sulphanilamide, or one of its congeners, is now indicated in this as in other forms of streptococcal infection.

RETRO-PHARYNGEAL ABSCESS

There are two forms—(1) Acute, and (2) chronic.

1. The acute form occurs in children up to the age of 3 or 4, but is far more frequently met with in the first 12 months. It is due to suppuration in the prevertebral glands, situated behind the posterior pharyngeal wall, which retrogress and disappear in later life. The abscess results from absorption of sepsis from the nares, naso-pharynx, or fauces, and is sometimes secondary to an infectious fever.

Though rare, the condition is an important one, for it may easily remain unrecognised in a young infant, and it is usually fatal if left unopened. The symptoms are fever and restlessness, a hoarse cry and croupy cough, with difficulty in swallowing and dyspnoea. Such symptoms should arouse a suspicion of retro-pharyngeal abscess, which may be seen on inspection as a rounded swelling of the posterior pharyngeal wall. The abscess is often very large, and must be freely opened in such a way as to avoid aspiration of the pus, without an anæsthetic, and with the child firmly held, either on the side with the face directed somewhat downwards, or on the back with the head hanging almost vertically. Recovery is rapid, and no after-treatment is required beyond attention to the enfeebled general health.

2. The chronic form, also, is found most frequently in children, but generally after the third year. It is of tuberculous origin, and is due either to tuberculosis of the prevertebral glands, or to caries of the cervical spine. The latter should be carefully excluded, for this abscess should on no account be opened through the mouth, as septic infection of the diseased bone will occur. The chronic glandular abscess, however, may be successfully opened and curetted by this route, though some surgeons prefer to treat them all by an incision behind the sterno-mastoid.

CHRONIC PHARYNGITIS

(PHARYNGEAL HYPERÆSTHESIA)

The symptoms of discomfort in the throat in the conditions grouped as chronic pharyngitis bear little relationship to the intensity of the changes seen on examination. Many people, especially heavy smokers, complain of no discomfort, in spite of showing decided chronic inflammation; whereas others, in particular dyspeptic or anæmic women or those at the menopause, suffer great discomfort, with no apparent local abnormality. Indeed, in many cases the condition is better described as pharyngeal hyperæsthesia; globus hystericus may be considered to be an extreme example of this hyperæsthesia.

Ætiology.—The causes of chronic pharyngitis are most often found in nasal disease, which produces inflammation of the pharynx by causing mouth-breathing, and by the irritation of discharges; incorrect production of the voice is an important factor which is often in its turn dependent on nasal obstruction. Unhealthy conditions of the teeth or tonsils are further causes, as are the inhalation of irritating dust and vapours in various occupations, tobacco smoke and over-indulgence in alcohol. A long list of constitutional affections is active in the ætiology, such as gout, rheumatism, dyspepsia, anæmia, cardiac disease, cirrhosis of the liver, chronic bronchitis and pulmonary phthisis.

Symptoms.—The discomfort may take the form of aching, fullness, or feeling of a lump, a hair, or a pricking. The voice has a dead tone, and there is usually much hawking and frequent swallowing. The sufferer often becomes depressed, and fears that he has cancer of the throat. The unpleasant sensations are markedly lessened after a meal.

The mucosa of the pharynx and palate is thickened, and there is a loss

of the finer modelling of the faucial pillars; the uvula is elongated, often slightly œdematous at its edges and tip, and fails to retract on phonation. The posterior wall is covered by a film of mucus, which puckers up and becomes more obvious on touching it with a probe or swab. The wall of the pharynx is traversed by enlarged venules, and sometimes it is set with slightly raised pink lenticular nodules of lymphoid tissue, constituting a variety known as *granular pharyngitis*. In other cases two elongated masses of lymphoid tissue appear behind and parallel to the posterior pillars; these are the "lateral bands," and this form is called *lateral pharyngitis*. *Pharyngitis sicca* is a dry glazed condition usually dependent on rhinitis sicca or atrophic rhinitis, and occasionally the crust formation of the latter disease extends to the pharynx, causing a genuine *atrophic pharyngitis*.

Treatment.—The most important part of the treatment consists in the detection and alleviation of the cause, and should begin with a careful examination of the nasal passages. Cases of pharyngeal hyperæsthesia without obvious local changes are often harmed, rather than helped, by local treatment which directs attention to their trouble. Tobacco should be given up, and alcohol in concentrated forms, indeed the latter should be abandoned completely in plethoric patients and where the pharynx is congested; condiments and highly seasoned food should be avoided; this type of patient is benefited by a morning dose of sulphate of soda or magnesia, a teaspoonful in a glass of hot water while dressing, or by one of the natural mineral waters. When the pharynx is dry, or covered with tenacious mucus, an expectorant mixture gives relief, such as tinctura ipecacuanhæ, min. 12, vinum antimoniale, min. 5, potassium iodide, grs. 3, syrup of tolu, min. 60, water, 1 fl. oz., three times a day. The throat may be sprayed with a warm alkaline saline lotion, and the same may be, with greater advantage, syringed through the nostrils. Of local applications in the form of paints, iodine is the most generally useful, and may be applied daily by the patient as Mandl's solution; iodine, grs. 6, potassium iodide, grs. 12, peppermint oil, min. 3, glycerin, 1 fl. oz.; a 5 to 10 per cent. solution of resorcin in glycerin may be employed, or, if a more astringent effect is desired, iron-alum gr. 60, in glycerin, 1 fl. oz.; or the physician may himself apply, once or twice a week, nitrate of silver, grs. 10 to 30 to the ounce of water. In many cases, the galvano-cautery is of great value; it acts as a counter-irritant and astringent, and should be applied lightly and with caution. Prominent granulations may be destroyed and enlarged venules obliterated by this means, but deep eschars should not be produced, and only a few applications should be made at one sitting.

KERATOSIS PHARYNGIS

In this condition a number of sharply defined projecting white or yellow nodules occupy the surface of the tonsils; they also occur, though less profusely, scattered over the lingual and naso-pharyngeal tonsils and on any lymphoid granules in the pharynx. They occur at any age after childhood, and usually in persons in a poor state of health. The causation is unknown; the nodules consist of heaped-up epithelium and detritus containing numerous micro-organisms of the kind ordinarily present in the mouth. They sometimes disappear quickly, in other cases they remain for many months, or they

may frequently recur. They produce no symptoms, or at most a slight discomfort, and are of interest chiefly because they are frequently mistaken for the exudation of chronic follicular tonsillitis. Once seen they can, however, be recognised at a glance, for they are hard and adherent, discrete and prominent, and occur beyond the limits of the tonsils, on the pharynx and base of the tongue. They are usually discovered accidentally by the patient, who is naturally alarmed at their appearance. They are quite harmless, and local treatment is useless, for they are removed with difficulty and usually recur; it is wise to reassure the patient by telling him these facts and, if any treatment be required, to trust to attention to the general health, a holiday and change of air.

SYPHILIS

The *primary* chancre occurs, though very rarely, on the fauces, the pillars, palate or pharyngeal wall, but usually on the tonsil. In this situation the disease is apt to pass unrecognised, for the symptoms are usually slight and the lesion masked by the general inflammation of the tonsil; the typical induration is often absent, but there is always a characteristic bubo behind the angle of the jaw.

SECONDARY SYPHILIS

Secondary manifestations in the fauces are a part of the normal course of the general disease and are intensely contagious.

Symptoms.—The subjective disturbances are usually limited to dryness and discomfort. Objectively there are two types of lesion, erythema and mucous plaque. The former is a patchy, dusky red rash, with well-defined margins, somewhat symmetrical, and affecting especially the anterior pillars and soft palate. It is particularly associated with the early secondary symptoms; whereas the mucous patch may be present at the same time or may be found later, together with tertiary manifestations. The mucous plaque occurs on the soft palate, tonsils and pillars; in appearance it is a dusky, slightly-raised patch, with a sharply defined red margin, the surface is covered by a delicate milky-white layer of superficial necrosis resembling a "snail-track" or, if rather thicker, looking as if it had been touched with nitrate of silver.

Diagnosis.—The appearances just described are so characteristic that they are of great help in the diagnosis of the general affection; if their nature should be misinterpreted, other secondary symptoms nearly always co-exist to establish the correct diagnosis.

Treatment.—General treatment quickly cures these secondary lesions, though they may reappear during the first two or three years. Of local treatment, abstinence from tobacco and alcohol is important, as are the careful use of a tooth-brush after every meal and the employment of a mouth-wash, such as peroxide of hydrogen or potassium chlorate.

TERTIARY SYPHILIS

Tertiary lesions usually occur about the third or fourth year after infection but may rarely be found within a few months or may make their appearance at any later time throughout the patient's life.

Symptoms.—Two principal forms may be described—(1) superficial ulcer, and (2) gumma.

1. The *superficial ulcer* may attack any part of the fauces, the posterior wall, tonsils, pillars or palate, a favourite site being the junction of the uvula with the edge of the soft palate. It has a flat base, with a smooth yellowish necrotic surface and a well-defined red margin, devoid of swelling or infiltration, and has a peculiar "serpiginous" contour as though marked out by segments of a series of circles.

2. A *gumma* is a localised infiltration which rapidly breaks down and exposes a deeply excavated circular ulcer covered with a thick yellow slough. One favourite site is on the posterior pharyngeal wall above the level of the palate, and another on the upper surface of the soft palate; in the latter situation nothing is seen from the mouth except a general dusky swelling of the palate until perforation suddenly occurs and irremediable damage has been done. After severe gummatous ulceration the resulting cicatricial contraction may bind the palate to the pharyngeal wall and partly or completely shut off the naso-pharynx from the mouth.

Of subjective symptoms, dysphagia may be very severe; nasal obstruction is present when the naso-pharynx is occluded by swelling or scarring; the voice is altered to a dead tone when there is nasal obstruction, or to the characters of a cleft-palate articulation if a perforation of the palate has occurred.

Diagnosis.—From an ulcerating malignant growth the diagnosis may be a matter of difficulty, especially as in syphilis the dysphagia may produce marked cachexia and loss of weight. The gummatous ulcer is excavated, covered by a dirty yellow adherent slough, its margin only moderately thickened, often overhanging, and surrounded by an area of deeply congested mucous membrane; the base of an epitheliomatous ulcer presents a nodular "cauliflower" aspect, and its edge is thick and everted; palpation with the finger is of great value, for the peculiar hardness of an epithelioma is highly characteristic. The superficial tertiary ulcer is usually easily distinguished from lupus, the ulcerations of which are surrounded by and dotted over with the characteristic granules, and the lesions of which occur on a pale mucous membrane, while manifestations of lupus are to be found elsewhere. Tuberculous ulceration of the fauces is superficial, but is more intensely painful than the superficial syphilitic ulcer, and is a terminal event in advanced pulmonary tuberculosis. Vincent's angina may closely resemble syphilitic ulceration of the tonsil, but is distinguishable by its more acute onset, raised temperature and tender glands. Actinomycosis, when it attacks the region of the tonsil, closely resembles an ulcerating gumma, especially as it improves under administration of iodides; the detection of the characteristic yellow granules will lead to their microscopical examination and recognition.

Treatment.—The most energetic general treatment with arsphenamine is necessary in cases of gummatous infiltration to prevent perforation of the palate or severe cicatricial deformity. Local treatment consists chiefly in the use of antiseptic mouth-washes and gargles. Orthocaine (orthoform) by insufflation is helpful when there is dysphagia. The daily application of 3 grains of calomel, sublimed by a spirit-lamp and insufflated from a glass tube, is to be recommended in severe cases of ulceration.

LUPUS AND TUBERCULOSIS

Lupus occurs most frequently in young women. It usually shows evidence of having spread from the nasal passages, and attacks first the uvula and soft palate, whence it spreads to the faucial pillars. It appears as a patch made up of minute reddish nodules, each containing the typical "apple-jelly" centre; the surrounding mucosa shows no sign of inflammation. A progressive superficial ulceration gradually occurs, and may cause destruction of the uvula and part of the soft palate, while elsewhere scarring becomes evident and may finally result in considerable deformity. The subjective symptoms are limited to a feeling of stiffness and discomfort. The diagnosis is generally easy from the characteristic appearance, the chronicity, and the presence of lupus in the nares and on the skin. Syphilis is more rapid and does not spare the bony palate, which is never attacked by lupus. Lupus in the pharynx is far more amenable to treatment than in the nose, and may be expected to improve under the general anti-tuberculous régime of good food and open air; arsenic in full doses is very valuable, beginning with 5 minims of liquor arsenicalis three times a day, and increasing the dose gradually to 15 minims. Tuberculin has proved disappointing. Of local measures multiple puncture with a fine galvanocautery point is most useful, and massive patches of infiltration may be curetted.

Apart from the latent tuberculosis of the tonsils associated with cervical adenitis, which has been referred to under chronic tonsillitis, tuberculous disease of the pharynx is a rare affection; it occurs as a late and terminal complication of advanced consumption. The onset is acute; the affected parts, especially the soft palate and faucial pillars, are covered with numerous tiny grey tubercles on a bright red mucosa which soon break down to form multiple superficial ulcers with a flat greyish-yellow base. Pain is intense and swallowing becomes well-nigh impossible; treatment must be directed to alleviating the distress with insufflations of orthocaine, lozenges of cocaine or morphine, hypodermic injections of morphine or diamorphine, and saline and nutrient enemata.

HAROLD S. BARWELL.

DISEASES OF THE ŒSOPHAGUS

THE NORMAL ŒSOPHAGUS

The act of swallowing occurs in four stages. The first consists in the voluntary propulsion of food from the mouth to the pharynx. The second is set in action by a reflex arising from the contact of food with the posterior wall of the pharynx, which leads to closure of the passages leading to the mouth, nose and larynx, together with a rapid peristaltic wave travelling down the constrictors of the pharynx, which is followed by the opening of the hitherto closed pharyngo-œsophageal sphincter formed by the lower division of the inferior constrictor. The third stage consists in the propulsion of the bolus

by a peristaltic wave down the œsophagus till it reaches the closed cardiac sphincter, the active opening of which constitutes the fourth and final stage of deglutition.

DYSPHAGIA

Dysphagia, or difficulty in swallowing, is generally the first symptom in diseases of the œsophagus. Owing to the fixed position of the œsophagus localisation of abnormal sensations is very accurate, and a patient generally points to the exact level of obstruction. In some cases, however, reflex achalasia or spasm of the pharyngo-œsophageal sphincter occurs simultaneously, so that the patient experiences difficulty in initiating the act of swallowing as well as feeling the obstruction in the passage down the œsophagus caused by the primary disease.

The causes of dysphagia can best be considered according to whether the difficulty is experienced at the upper extremity, near the middle, or at the lower extremity of the œsophagus; the last is the most common.

(a) *Pharyngo-œsophageal dysphagia*.—This is most commonly a result of the upper dysphagia with anæmia syndrome. In rare cases it is hysterical and it may also occur in various organic nervous diseases. Upper dysphagia may be caused by epithelioma, especially in women, and by a pharyngeal pouch, especially in old men.

(b) *Mid-œsophageal dysphagia*.—This is almost always caused by epithelioma. External pressure by an aneurysm or mediastinal tumour rarely causes dysphagia.

(c) *Lower œsophageal dysphagia*.—Dysphagia at the lower end of the œsophagus is most frequently caused by achalasia of the cardia and by epithelioma of the œsophagus. Next most frequent is the dysphagia caused by spasm secondary to peptic œsophagitis and œsophageal ulcer, and by carcinoma of the fundus of the stomach. Lastly, the dysphagia may be due to cicatricial stenosis secondary to peptic ulcer or to the phlegmonous œsophagitis resulting from the swallowing of boiling water or corrosive poisons.

HYSTERICAL DYSPHAGIA

Theoretically there is no reason why hysterical dysphagia should not develop in the form of paralysis or inco-ordination of the voluntary muscles concerned in the first two stages of swallowing, in which food passes through the sensitive bucco-pharyngeal cavity. It would, however, be very unlikely to develop in the œsophagus itself or at the cardia, where the passage is entirely independent of voluntary action and under ordinary conditions is not felt, the food disappearing into the void after passing the pharyngo-œsophageal sphincter, unless it is very cold, very hot or in large lumps.

Hysterical dysphagia is, however, rare. The majority of cases so diagnosed are examples of the upper dysphagia with anæmia syndrome, and others are really suffering from myasthenia gravis. It develops in patients who have become nervous for various reasons, when some trivial incident draws their attention to the voluntary but normally automatic act of swallowing. Much weight is lost. Recovery always follows simple psychotherapy by explanation and persuasion.

DYSPHAGIA IN ORGANIC NERVOUS DISEASES

Dysphagia may occur in various organic nervous diseases as a result of paralysis of the muscles concerned in the first and second stages of swallowing. The œsophagus itself and the cardiac sphincter are never involved. In diphtheria the toxin ascends by the lymphatics of the nerves from the site of the lesion to the central nervous system, where it puts the cells of the corresponding nuclei out of action. The paralysis of the soft palate, which results in regurgitation of food through the nose, and the rare pharyngeal paralysis which results in severe dysphagia, occur therefore only in the common faucial diphtheria and not when the primary focus is in a wound, the conjunctiva or elsewhere. The paralysis is nuclear in origin and generally develops in the second week, in contrast with the more widespread paralysis caused by diphtheritic polyneuritis, which appears between the third and sixth weeks.

In the motor neurone disease, which includes progressive muscular atrophy and amyotrophic lateral sclerosis, dysphagia may occur if the vagal nucleus is involved in the last stages of the common form beginning in the muscles of the hands. It always occurs in progressive bulbar palsy, the form which begins in the bulbar nuclei. Though myasthenia gravis is a primary muscular disease, it gives rise to a simple upper dysphagia, in which the first as well as the second stage of swallowing is affected. In the motor neurone disease the slowly progressive paralysis is unaffected by any treatment, and there is no variation in the course of each day, so that once nasal feeding is begun it has to be continued until death, which is not likely to be long delayed. In myasthenia gravis the dysphagia increases in severity as the day goes on, and considerable spontaneous improvement may occur from time to time, so that a patient who has had to be fed temporarily by nasal tube may later be able to swallow quite well for weeks, months or years. Improvement in swallowing may be a direct result of the complete rest given to the muscles of deglutition by nasal feeding. Slight dysphagia can sometimes be controlled like other symptoms by $\frac{1}{2}$ to 1 grain of ephedrine taken an hour before meals. In severe cases an injection of 1 to 2 mgm. of prostigmine may make swallowing possible for four or five hours, but it should be used only to tide over a period of great difficulty and not for long periods, as it may lead to increased weakness after the effect of the individual dose wears off. Dysphagia is also a symptom of the acute bulbar paralysis which may follow vascular or inflammatory lesions involving the nucleus ambiguus.

In all forms of dysphagia due to organic nervous disease food of porridgy consistence is most easily swallowed, as fluids require more rapid action and lumps more powerful action than soft food.

UPPER DYSPHAGIA WITH ANÆMIA

(PATERSON'S (SO-CALLED PLUMMER-VINSON) SYNDROME.¹)

The "upper dysphagia with anæmia syndrome" is much the most frequent cause of difficulty in swallowing involving the junction of the pharynx and

¹ This syndrome was described by D. R. Paterson in 1909 and more fully in 1919. Vinson wrote about it in 1922 and referred to unpublished work of Plummer in 1914. Paterson's description was more accurate than Vinson's, so that the designation "Plummer-Vinson syndrome" has no justification.

oesophagus. It occurs in about 15 per cent. of cases of the simple achlorhydric anæmia (also known as hypochromic or microcytic anæmia (*vide* p. 503), which is common in women, but very rare in men. The syndrome is the direct result of iron deficiency, which causes not only the anæmia, but also atrophy of the mucous membrane of the tongue and pharynx. The atrophy of the pharyngeal mucosa results in a loss of sensibility, so that the afferent side of the reflex upon which the second stage of swallowing depends is impaired. The orderly activity of the muscles involved in the complicated act is disorganised and swallowing becomes difficult or impossible. The pharyngo-oesophageal sphincter is particularly involved, the normal relaxation which allows the passage of food from the pharynx into the oesophagus failing to take place (achalasia) or being actually replaced by spasm.

The iron deficiency is a result of a diet containing too little meat and green vegetables, generally associated with achlorhydria, which interferes with the adequate preparation for absorption in the intestines of such iron as is present in the food, and occasionally with small intestine disorders which prevent its complete absorption. In many cases there is also excessive loss of iron from menorrhagia.

Symptoms.—The patient, generally an edentulous woman between 25 and 50 who has been in poor health for a long period owing to the presence of anæmia, gradually finds difficulty in initiating the act of swallowing, especially of solids. Sometimes, however, the dysphagia begins quite suddenly, and it may occur intermittently. Severe cases in which dysphagia is the main symptom are rare in comparison with those in which it is so slight that the patient does not mention it unless directly cross-questioned. The dysphagia is associated with atrophy and sometimes inflammation of the mucous membrane of the tongue and the pharynx. An atrophic condition also involves the lips, which are thin and inelastic with cracks at the angles of a narrowed mouth. Achlorhydria is frequently, but not always, present, and the spleen is occasionally enlarged. The nails are often thin, brittle and spoon-shaped.

The X-rays reveal no abnormality, and the oesophagoscope shows nothing more than an atrophic, inelastic condition of the pharyngeal mucous membrane, which may contract and aggravate the dysphagia by adding a mechanical obstruction to the neuro-muscular disorder.

The atrophic condition of the mucous membrane predisposes to epithelioma. About 50 per cent. of women with cancer of the mouth and a still larger proportion of those with cancer of the hypopharynx and upper end of the oesophagus give a history suggestive of the syndrome. The fact that the latter is almost confined to women probably explains why 80 per cent. of cases of epithelioma of the post-cricoid part of the pharynx, which always spreads to and obstructs the mouth of the oesophagus, occur in women, whereas at least 80 per cent. of cases of cancer of the middle and lower end occur in men.

Treatment.—A large mercury bougie should be introduced into the oesophagus from time to time until the dysphagia disappears. The anæmia responds to treatment with large doses of iron; liver is without effect, except in the rare cases in which it is Addisonian. The atrophic condition of the mucous membrane also responds to iron therapy even if there is no anæmia.

ACHALASIA OF THE CARDIA (SO-CALLED CARDIOSPASM)

Ætiology.—Achalasia of the cardia may begin at any age, but most commonly in adults, and males and females are equally affected.

Pathology.—The hypertrophy of the muscular coat of the œsophagus, which is always present, indicates that violent efforts must have been made to overcome some obstruction.

As no organic obstruction is ever found after death it was at first thought that the spasm of the cardiac sphincter was present, and the condition was called *cardiospasm*. As the symptoms may be present without intermission for many years before death, hypertrophy of the cardiac sphincter should result from the long-continued spasm. In very few autopsies, however, has there been any hypertrophy, and in several cases in which the

cardiac sphincter, which is normally about one inch long and corresponds with the whole of the abdominal œsophagus, was exposed by operation, the

muscle was found to be unusually thin. I believe that the obstruction is caused not by spasm but by achalasia (α , not; $\chi\acute{\alpha}\lambda\alpha\sigma\iota\varsigma$, relaxation), or absence of the normal relaxation of the cardiac sphincter, which should occur when each peristaltic wave reaches it (Figs. 15 and 16). Food stagnates in the œsophagus, which dilates as more and more collects in it; the distension of the œsophagus acts as a powerful stimulus to peristalsis, which is excessively violent and continues at intervals throughout the day. This is the cause of the hypertrophy.

Further evidence that the condition is due to achalasia and not to spasm is afforded by the

fact that, although strong peristaltic waves are unable to overcome the obstruction, the weight of an indiarubber tube filled with mercury is

FIG. 15.—Diagrams of normal swallowing as seen with the X-rays in successive seconds. OO, œsophagus; B, bolus of food; CC, cardiac sphincter; DD, diaphragm; S, spine; H, heart; F, gas-containing fundus of stomach.

FIG. 16.—Drawings from a case of dilated œsophagus secondary to achalasia of the cardiac sphincter. (a) Dilated œsophagus filled with a 7-inch column of opaque food; sphincter closed. (b) Opaque food passing into stomach through sphincter which has opened after additional food has raised column in œsophagus above 7-inch height. (c) Return to condition of (a) after excess of food over the 7-inch column has entered stomach. Note absence of gas-bubble from fundus of stomach.

sufficient to cause it to drop into the stomach, the actual passage through the cardiac sphincter being often inappreciable to the hand holding the mercury bougie, which can be withdrawn with equal ease. It is not gripped, as the finger is gripped when it enters or is withdrawn from a spasmodically contracted anal sphincter.

The achalasia is a result of inflammation, fibrosis or simple atrophy of the ganglion cells of the myenteric (Auerbach's) plexus, which form a relay station for the vagus on its way to the muscle fibres of the œsophagus. The vagi themselves are unaffected.

The dilated œsophagus may be able to hold as much as two pints, and its circumference may exceed 6 inches.

Symptoms.—Achalasia of the cardia generally develops gradually, a slight attack, lasting for a day or two, being followed by a period of freedom for a few days or even several weeks or months. Attacks then occur at gradually shorter intervals, until finally the condition becomes permanent. The patient feels as if the food "sticks." He often recognises that the obstruction is beneath the lower end of the sternum, but sometimes the sensation is felt in the upper part or middle of the chest. Sometimes actual pain is produced. Salivation occurs in every case.

As a rule the patient voluntarily relieves his discomfort within a few minutes of finishing a meal by bringing up the greater part of what he has eaten mixed with saliva. He realises that this comes from his chest and not his abdomen, and, unlike true vomiting, it is not associated with nausea.

The weight of the column of food in the dilated œsophagus after a meal is sufficient to force a small proportion of the fluid present through the cardia as a very narrow stream; but as soon as the height of the column falls below a certain point, generally about 7 inches, or the individual lies down, the pressure becomes insufficient and the flow ceases (Fig. 17). Consequently, stagnating food mixed with mucus is always present in the œsophagus, and a considerable quantity can be removed from it even after a fast of 24 hours. No regurgitation occurs on lying down as the pharyngo-œsophageal sphincter is always, as in normal people, closed except during the act of swallowing.

The œsophagoscope shows that the entry to the cardiac sphincter, which is generally at the level of the diaphragm but may be within the thorax or within the abdomen, is completely closed. The mucous membrane may be normal, but owing to the prolonged stasis of food it is often chronically inflamed, especially in the lowest part, and there may be superficial erosions.

In the absence of treatment the general health remains good in spite of the fact that weight is often rapidly lost. At a certain stage a condition of equilibrium develops. Though the diet has to be limited the patient loses no more weight, and though he is less strong than formerly, he may continue to live in this condition for many years and attain old age.

Diagnosis.—The patient's description of his symptoms is generally so characteristic that a diagnosis of obstruction in the region of the cardia can be made with a considerable degree of probability. It is next necessary to decide whether this is due to achalasia, cancer, or spasm associated with œsophagitis or peptic ulcer. The absence of pain and of serious constitutional symptoms in spite of rapid loss of weight, the comparatively early age of many patients, and, in cases in which an early diagnosis has not been made,

the long duration of the illness point to achalasia rather than to growth. The diagnosis is confirmed by the X-rays: in achalasia the shadow of the dilated œsophagus narrows abruptly and ends at the entry into the sphincter, either on a level with the diaphragm or a short distance above or below it. As each additional quantity of food is swallowed, a narrow and uniform channel is seen for a moment to join the œsophagus with the stomach before the sphincter closes again. In peptic ulcer of the lower end of the œsophagus the sphincter remains open, but a narrowing is seen just above as a result of spasm with or without cicatricial contraction, and the round crater of the ulcer may be recognisable. In carcinoma the lumen of the cardiac sphincter is replaced by an irregular channel which extends a varying distance up into the œsophagus, the unaffected part of which is never as dilated as in achalasia, and except in the later stages the opaque fluid continues to pass slowly through the narrow irregular channel into the stomach till the œsophagus is empty, whereas it is never empty in achalasia. If there remains any doubt about the diagnosis this can generally be settled by inhaling amyl nitrite, which results in dilatation of the sphincter and evacuation of the œsophagus. Further evidence pointing to achalasia is the ease with which a mercury tube passes through the cardia in contrast with the complete obstruction offered to its passage by a growth. Lastly, occult blood is present in the stools in cancer, but never in achalasia.

Prognosis.—If the condition is recognised at the onset of symptoms, a permanent cure often results from treatment, but if treatment is instituted only after the œsophagus has become dilated, cure as distinct from mere relief of symptoms is less likely to be obtained. In the absence of treatment death has occurred at an early stage in very acute cases; but more often the patient survives for a considerable period, even for forty years. In rare cases a diverticulum may form in the lower end of the dilated œsophagus or cancerous degeneration of a wart developing on the chronically inflamed mucous membrane may occur. In long-standing cases respiratory complications may result from pressure by the enormously distended œsophagus, or from regurgitation of the œsophageal contents into the pharynx and aspiration into the lungs.

Treatment.—Nitrites are the only drugs which cause relaxation of the closed cardiac sphincter. Unfortunately the effect is so evanescent and the general symptoms which result from inhalation of amyl nitrite, which is the most effective, are so unpleasant that they are rarely of any use. The simplest and most effective treatment is by means of a series of mercury bougies, the smallest of which is 24 and the largest 34-gauge. They are made of rubber tubes closed at the top and with a rounded lower end, and are half-filled with mercury. Three or four of increasing diameter can generally be passed at the first sitting. Afterwards only the largest bougie which the patient can himself pass should be used, preferably 34-gauge. It drops easily through the cardia and requires no pushing. It is kept in position for as nearly a quarter of an hour as possible. The patient feels relieved and realises that "the passage is clear" as soon as it is withdrawn. It should be passed immediately before meals; the food then enters the stomach without difficulty. In very early cases the tube may only need to be passed once. Generally, however, the tube had to be passed before each meal at first, then once a day, and gradually less often, till finally it is used only at rare intervals when the patient feels that some slight obstruction is returning. In chronic cases, which are always
